"Matter is, as it were, the plaything of force"—this evidently Prof. Pearson regards as his trump card. Now these words—and note the "as it were"—occur in the discussion of Newton's laws of motion, and are obviously suggested by Newton's own anthropomorphic language. But they can give rise to no misapprehension in the mind of one who is reading Prof. Tait's "Properties of Matter" for profit. In the light of the introductory chapter there is really no room for other than wilful misrepresentation of Prof. Tait's position. Moreover, it is positively astonishing to find an author, who has no slender claims to the title of historian, confessing his ignorance of Prof. Tait's lecture on "Force," delivered before the British Association in 1876, and published in NATURE, vol. xiv. (see also "Recent Advances," third edition, and Maxwell's "Life," p. 646). That lecture was, we think, the first popular exposition of the subjectivity of force. The recognition of this truth was, of course, a natural consequence of the remarkable series of discoveries which brought home to the mind that energy was physically as objectively real as matter. We certainly did not need to go all the way to Berlin to learn it. C. G. K.

On the Line Spectra of the Elements.

I OBSERVE from Prof. Runge's last letter that on one point I was led into misinterpreting his meaning by his having used the letter *j* in his second formula on p. 100 (NATURE of June 2) in a sense different from the only definition that had been given of that symbol, viz. the jot of time—the time that light takes to advance one-tenth of a millimetre in the open æther. The period of time represented by *j* is as determinate as a day or hour. With it, Prof. Runge's equation represents one definite discontinuous motion along the sloping sides of the teeth of a particular saw, and this is what I understood by it. I perceive now that he intended *j* to be interpreted in a new sense, and meant the equation to represent uniform motion in a straight line to an *indefinite* distance.

If all that Prof. Runge wishes to point out is that motion along an orbit that extends to infinity must be either wholly incapable of being represented by a Fourier's series, or at least must contain a component of that kind, this is both true and obvious; and the instance he gives (which is, in fact, uniform motion to an unlimited distance along a straight line) is a case in point. But it should be added, no such component of the motion of an electric charge which does not yield to Fourier's theorem can produce any periodic disturbance in the æther: in other words, *it would not contribute anything to the spectrum.* Accordingly, any such part of the motion—for instance, the advance, in common with the rest of the solar system, of the electrons within the molecules of a gas on the earth, at the rate of eight miles a second, towards the constellation Hercules, which is the precise kind of motion that Prof. Runge adduces as an instance—has nothing whatever to do with the subject of my memoir, which is an investigation into the cause of double lines *in spectra.* It should further be added that unlimited motions of any kind have nothing to do with motions going on *within molecules*, to the investigation of which chapter iv. of my memoir is devoted, and that any discussion of them there would have been out of place.

Hence, to represent as a defect which vitiates my reasoning, as Prof. Runge does, that I have omitted in that chapter to refer to the motions which are not resolvable by Fourier's theorem, is, I submit, not legitimate criticism, especially as the matter, beside being irrelevant, is obvious; and I also submit that to say "A plausible suggestion about the movement of the molecules ought to explain more than one of the observed phenomena" (NATURE, April 28, p. 607) is not criticism at all. We must use the data furnished by our observation of nature to carry us as far as they will go in the interpretation of nature, and not refuse to employ them to that extent because they do not enable us to get further.

G. JOHNSTONE STONEY.

9 Palmerston Park, Dublin, July 2.

Range of the Sanderling in Winter.

As my little contribution to the *Records of the Australian Museum* has been honoured by a notice in NATURE (*suprà*, pp. 177–78), I must ask leave to qualify two statements therein made. Since I wrote it I have become aware that Dr. Finsch had a specimen of the Sanderling (*Calidris arenaria*) brought to him at Bonham Island, one of the Marshall Group, which lies within the tropics (*Ibis*, 1880, p. 331); and, after the publication of Mr. Everett's list of the birds of Borneo in 1889, that gentleman announced the occurrence of this species at Baram, on the north-east coast of that island (*Ibis*, 1890, p. 465). ALFRED NEWTON.

Magdalene College, Cambridge, June 25.

Immunity of the African Negro from Yellow Fever.

DR. CREIGHTON will find that on p. 51 of a report dated 1890, "On the Etiology and Prevention of Yellow Fever," Dr. George M. Sternberg (Lieut.-Colonel and Surgeon U.S. Army) makes the following statement:—

"It has been asserted that the negro race has a congenital immunity from yellow fever, but this is a mistake. The susceptibility of the negro is, however, much less than that of the white race. Amongst those attacked the mortality, as a rule, is small."

He will also find the subject discussed on pp. 166–67 of "A Contribution to the Natural History of Scarlatina," by Dr. D. Astley Gresswell (Clarendon Press, 1890). Dr. Gresswell writes thus:—

"The African negro of pure descent was supposed to be insusceptible to the virus of yellow fever and of malaria. It is said, however, that when these affections are prevailing in a virulent form the negro does become infected and manifest such infection. This would suggest that the almost complete immunity in the case of the negro has been acquired. Moreover, the fact that negroes of pure descent are more likely to manifest the symptoms of yellow fever on exposure to the poison after they have passed some years or some generations in more temperate latitudes, in which the disease is not indigenous, suggests that in order to maintain this degree of immunity it is necessary that the negro should continue to live in localities in which the virus exists; in other words, that the individual or the race should be repeatedly subjected to the virus. It may, in fact, be questioned how far, in regard to these diseases in man, susceptibility differs independently of protection acquired by previous subjection to the action of the virus or its products; though natural selection may (as certain facts indicate) have acted more directly. Indeed, it is quite possible that protection acquired by previous infection is much more frequently a cause for benignity or only partial susceptibility in the case of these and other infection-diseases than is generally allowed for."

I do not think I can with advantage add anything to these quotations. YOUR REVIEWER.

A Solar Halo.

IN connection with the heavy thunderstorms further south, possibly, there was here the most brilliant solar halo on the 29th which I have seen. The wind was easterly all the time, causing sea-fog-like clouds in the morning, which dissipated by degrees about 10, but I did not notice the halo before 10.45, nor after 3.30 or 4 o'clock. It was certainly gone at 5.

Though a complete halo at 11, it was far intenser above and below, the north-west and south-east octant especially. By 1 o'clock this had shifted to the north-east and south-west octants.

Between 11.45 and 12 the south-east octant of the outer halo (red inside) was also visible.

Until 1 o'clock the figure was practically circular, the inner space being remarkably free of colour, the blue of the sky assuming an ashy grey tint. By 2 the figure was elliptical, the long axis horizontal, and the halo *not complete*. The ellipticity increased as the sun sank. Hence the visible part was evidently formed of the *tangent arcs*. No doubt the intense brilliancy near noon was due to these arcs practically coinciding with the ordinary halo, because of the sun's great altitude.

EDWARD HAMILTON.

Are the Solpugidæ Poisonous?

AT a recent meeting of the Linnean Society (June 2), I had the honour of exhibiting the jaws, claws, and hairs of a species of Galeodes from Tashkend, in order to show certain peculiarities, which perhaps throw light on the question as to whether these animals are poisonous or not.

Murray, in "Economic Entomology," says: "Their bite is said to be venomous, and even dangerous, but proof of this is wanting."

It is, further, always the natives in both the Old and New Worlds where this "spider" occurs who give it its bad reputation, and always the European immigrant or settler who either doubts or even positively denies it.

In spite of the well-known fact of the persistence of groundless terrors in the minds of uncivilized peoples, I should still be inclined to think that, in a case of this kind, which is one of raw experience, the natives would probably be in the right.

Dufour, in his monograph of the Algerian species (*Mem. p. à l'Institut de France*, xvii.), after describing a serious case arising from a Galeodes bite, having failed to find any poison-glands or apparatus, leaves the mystery to be solved by others.

Croneberg (*Zool. Anzeiger*, 1879) claimed to have discovered the poison gland in a long coiled gland, which he says opens at the tip of a lancet-shaped process at the junction of the palp with its basal or maxillar portion. As far as I can make out, this gland is the homologue of the coxal gland of the other Arachnids. This would not preclude the possibility of its being a poison gland. On the face of it, however, I should not expect to find the opening of the poison gland in this comparatively awkward place. In a creature so armed for attack as Galeodes, one would expect the venom to take a more prominent place in the offensive armoury.

Examination, on immersion in clearing media, shows—

(1) That the tips of the jaws are not only traversed by a canal opening to the exterior, but are covered with multitudes of fine pores, which can be traced with a low power through the thick chitin.

(2) The claws are also open at the tip, while the shaft of the claw seems filled with a glandular mass of tissue provided with tracheæ. These claws are terrible weapons of offence; the articulating joint at the end enables them to anchor themselves in the body of the prey.

(3) Around these claws are sharp hairs, which appear, like the claws, to be open at their tips. It is obvious that the tighter the claws draw themselves into the flesh, the deeper would the pointed hairs at their base penetrate, and, if poisonous, increase the deadly nature of the attack.

(4) Leaving the spines on the limbs, and the long, thin apparently tactile hairs out of account, the hairs on the legs and back are, as a rule, forked at the tip, as has been already described by Dufour. Up to the fork they are hollow, like those round the claws. My suggestion is that these are like buttoned rapiers. They are harmless until the animal is seized. The fork prevents the hair from penetrating until the pressure is great enough to snap off the tip. Small mammals and birds would soon learn not to try to chew up or swallow a Galeodes. If this suggestion is correct, the action of the forked hairs may be compared with that of the stinging hairs of the common nettle.

(5) Here and there are long hollow hairs, with the tips swollen out into a thin bubble-like expansion of the chitin. These hairs may be abnormal. I found five or six in all, and chiefly on the palp. They seem to indicate a tendency of fluid to flow down the hairs.

The openings at the tips of the claws are quite in keeping, morphologically, with those at the tips of the hairs. Claws are but highly developed hairs. The jaws, however, are modified joints of limbs. We have, therefore, to interpret the central canal (?) and the pores which open at and around their tips, as the canals which run through the cuticle into the hairs. We find that, as we recede from the tips of the jaws, the open pores cease, and the hairs commence, each with its central canal continued through the cuticle.

As to the nature of the poison which I suggest flows through these apertures, I am inclined to consider it, in the presumed absence of specialized glands, as a product of the hypodermal cells, perhaps even of those which secrete the hairs themselves. At the tips of the jaws, where the hairs have disappeared and only their pores remain, these cells could be specialized for this purpose alone. In the claws there seems to be a mass of cellular tissue, which would also be a derivative of the hypodermis, and may be solely taken up with the secretion of poison.

One other point remains to be mentioned, viz. the mechanism for the movement of the end joint of the claw. Articulated hairs are common among the Polychæte Annelids, but the exact mechanism is not visible. This large claw of Galeodes may explain these cases. We should naturally not expect a muscle fibre in a hair. The actual mechanism is very simple. Along one side of the claw the chitin splits, for, say, three-fourths of its proximal length, to form an inner and an outer layer. A very slight differentiation of the flexor muscles of the claw would allow of a few fibres being attached to the inner layer. A pull at the inner strip of chitin bends round the tip of the claw, invaginating a small portion of the outer layer, which thus forms a collar round the base of the joint or "nail" as some call it. The bending of the claw would almost necessarily compress its fluid contents, some of which might escape through the opening at its tip.

Until the question as to the poisonous nature of Galeodes has been *experimentally* settled, these observations seem to have some weight in the affirmative scale.

HENRY BERNARD.

Streatham.

Death from Paraffin, and Members of Parliament.

NOTWITHSTANDING the enormous development which has taken place in recent years in gas and electricity, there can be no doubt that oil lamps light the homes of a larger number of persons *throughout the world* than any other illuminant. Even in the United Kingdom alone it has been estimated that over 10,000,000 lamps are in use. No wonder, then, that newspaper readers are every now and again startled by the recital of terrible accidents, too often resulting in agonizing death. Mr. Alfred Spencer, of the London County Council, stated at the inquest on the late Lord Romilly that he estimated that there were 300 deaths a year caused in this country by unsafe lamps. Mr. Shean, of the Fire Brigade Association, expressed the opinion that 10 per cent. of fires are caused by paraffin lamps; and Captain Shaw, the former Superintendent of the London Fire Brigade, reported 156 fires in one year caused by the upsetting of lamps in London. Will a friend to humanity in each constituency ask the candidates, whether Liberal or Conservative, to pledge themselves to support a short Act of Parliament compelling every lamp to have affixed to it an automatic extinguisher, as recommended in the reports of Sir Frederick Abel, Mr. Boverton Redwood, and Colonel Majendie, or must we wait until a Bishop or a Royal Princess is burnt to death?

HUMANITY.

ON THE CAUSES OF THE DEFORMATION OF THE EARTH'S CRUST.

Mountain-making.

BY eminent geologists it has been shown that the contraction hypothesis is not sufficient to account for the observed deformations of the earth's crust. We are obliged to look for other causes of deformation.

The form of a cosmic body must be irregular if the masses are unequally mixed. Already in the liquid stage under this condition a geoid is formed. The radius with dense material must be shorter, so much as to equilibrate the higher regions with less density.

This cause of constant irregularity is not sufficient to explain the existing differences of level. In fact, depressions and elevations are not the result of a constant equilibrium; they are not permanent. Sedimentation and erosion disturb the mechanical and the thermal equilibrium and cause a continual deformation of our planet. Another cause of deformation is found in the continual shifting of material. Accumulation of eruptive material and of sediments (loading) on one side, and erosion (disburdening) on the other side, cause deformations of the earth's crust. If the plasticity of the cosmic body is great, the surface of the burdened and disburdened regions has the tendency to remain nearly level—a quasi-hydrostatic (a "magmastatic") equilibrium will dominate.

As the material of our earth is not very plastic, and as other causes of deformation have a contrary effect, it is natural that geological facts are not in accordance with this hypothesis.

Contradictory to this hypothesis are the facts (1) that subsidence does not continue as long as sedimentation goes on; (2) that sinking often is considerable, though the loading is slight; (3) that in many cases enormous loading does not produce a depression of the earth's crust (volcanic chains growing up on a highland).

The Thermal Theory.

The constant disturbance of thermal equilibrium is of the highest importance. Sedimentation causes an ascending movement of the geo-isotherms: expansion and general elevation. If the dilatation is concentrated, there may result a fold-chain (Hall, Reade). The hypothesis is supported by the fact that the elevation and folding always drives up sediments, which were formed immediately before the orogonic movement. The mountains grow up from a shallow sea, they are never generated in the middle of a continent, which might as well occur according to the contraction-hypothesis.

Messrs. Fisher, Hutton, and Reade have considered the thermal effect, and agree that it is sufficient to produce considerable deformations. But to produce a mountain-chain of some 1000 m., we must suppose a concentration of the effect in one zone, as long as we, according to Mr. Reade, consider only the effect of thermal expansion in the earth's crust.

As physical geology considers the earth as a rigid body (the plasticity, according to Mr. G. Darwin, being that of steel) there is no reason why the thermal expansion ought not to proceed through the rigid magma to the region of constant temperature. The increase of temperature being 3° C. for 100 m., the temperature at the depth of 40 km. = 1200° C., at 50 km. = 1500° C. After sedimentation of 10 km. the base of the sediments is warmer by 300°. The underlying masses are equally warmer by this quantity.

The linear expansion of rocks per 100° C. is nearly = 1 per mille, *i.e.* 1 metre per km. In our case the expansion is = 3 m. per km. Lateral expansion being impossible, it results in a vertical elevation of nearly 1 per cent. The *crust* would be elevated through the full expansion by 500 metres.

If we consider the thermal expansion proceeding to a depth of 500 or 1000 km. through the rigid magma, we find that indeed highlands and chains of some 1000 m. may be driven up, even if we do not suppose a concentration of the thermal effect on a restricted zone.

Yet certain facts are not in accordance with the theory thus formulated. (1) Elevation and mountain-making is not a slow and constant process, but it is executed in a short time (relatively). (2) Folding in some cases does not reach to a considerable depth, but we often meet undisturbed masses below the folded complex. These facts induce us to modify the hypothesis.

Messrs. Gilbert and Suess have shown that the movement of folding is horizontal and superficial; we may consequently ask whether folding may not be caused by a *gliding* movement (see my "Theoretical Geology").

If we deposit under water sediments of great plasticity, and if we incline afterwards the masses to the extent of 5° or 10°, there succeeds a gliding movement, especially if the sediments partly emerge from the water-level, and if occasional shaking (earthquakes) occurs.

The gliding masses form a fold-chain. The Silurian of Christiania is intensely folded, but it rests on an undisturbed base (Brögger). The folded Jurassic strata of the Weser chain likewise repose on an unfolded base. In such cases it is impossible to derive folding from a general contraction, nor can we explain the quiet base by supposing a concentration of thermal expansion in certain districts. The existence of a quiet base is explained only if we admit folding to be in such cases a gliding process.

The fact that folding in nature is accompanied by emersion is in accordance with these views.

Contradictory to this hypothesis seems the fact that the hypothetical land (from which the folded sediments were pushed towards the lowland) in the back of the chain is often wanting, and that in its place a (marine or a terrestrial) depression exists. This objection disappears if we pursue the process, and we find that this seemingly contradictory fact indeed must result: partial cooling causes local depression. Erosion has the same effect. If 1 km. (vertical measure) of rock mass is denuded, the temperature of the new surface is lower by 30° C. than it was at this point before erosion occurred. This cooling propagates into depth, and the denuded land gets depressed.

The highland, from which the sediments glide away, must sink down in course of time. The Jura is pushed towards the French plain; in the back is situated the depression of Neuchatel. Here, according to the deduction, existed a highland, which subsided in consequence of cooling. Between the fold-chain and the depressed district are situated deep ruptures, along which earthquakes occur as long as the depression goes on.

East of the Appalachian Mountains, as late as the end of the Palæozoic era, a highland was situated, wherefrom the detritus-masses were transported into the Appalachian sea. Afterwards the Carboniferous emersion occurred (in consequence of thermal expansion) and the Palæozoic sediments were pushed towards the western lowland; here the Appalachian chain was generated. Erosion and consequent cooling, instead of the old elevation, caused a depression in the eastern region, which got inundated by the ocean.

In course of time the adjoining districts have changed parts. In the lowland a chain is driven up and the old highland sinks down.

Eruptive districts form depressions with growing accumulations. The thermal effect in course of time leads to an opposite movement. Material of 1000° C. flows through many fissures and covers the surface. The eruptive region, in consequence, gets heated in a higher degree than by simple sedimentation. The period of depression in this case, too, in course of time, gives way to a contrary movement.

It is obvious that elevation and subsidence, in volcanic as well as in sedimentary districts, must alternate, as we indeed observe. Compression, metamorphism, and loading cause a negative movement in the sedimentary districts (geosyncline); warming causes elevation; erosion again creates subsidence. These positive and negative factors at different times have different values, and partly compensate each other. Therefore elevation and subsidence are often observed to alternate.

The greatest contrasts must occur where a highland joins the sea; here sedimentation and erosion cause a considerable shifting of material; loading and unloading, as well as great thermal contrasts, dominate in these regions.

The positive and negative movements of the sea-level are not important; but the amplitude of deformation at the boundary between high land and sea is in some cases as great as 20,000 metres.

The hydrosphere is relatively constant, whereas the crust executes oscillations of long duration and great amplitude.

If we want to study in an experiment the formation and motion of a lava-stream, it cannot be our wish to observe the motions of an enormous quantity of a body as viscid and as hot as lava through long time; that would be mere observation, and not experiment. In a real experiment we observe the motion of a small quantity of a less rigid material for some hours or days.

If we observe in nature folded strata of hard sandstone and of soft shale or clay, we shall be satisfied to imitate the deformation of the latter masses; and instead of the hard sandstone, we will take substances as unplastic, but so brittle that they yield to the small forces employed in our experiment.

So we may produce on a small scale, with application of little force and in a short time, the same effect which we observe in nature on a large scale.

If we succeed in producing experimentally the same phases of deformation, the same mechanical effect as in nature, if we see fold-chains and complicated eruptive massives growing up with their characteristic features, we shall be obliged to attribute to these experiments a high importance for mechanical geology.

In my experiments I evaporated muddy material (clay, mud) or plaster of Paris, which consolidates slowly in consequence of an admixture of glue. The strata were differently coloured: some thin strata, consisting of plaster-powder, were brittle, and underwent ruptural deformation, whereas the other masses showed plastic deformation. The whole system reposed on a base, which, according to the plasticity of the material, was inclined by 5° to 15°.

As soon as the inclination attained a certain limit, the whole complex begins to glide towards the lowland. The sediments get folded to a considerable depth; faults occurred between districts of diverse motion. The gliding deformation occurred rapidly whenever the base was shaken slightly (earthquakes). The experiment being finished, we let the masses consolidate; afterwards we may prepare profile-cuts, which may be executed with the saw, if we evaporated plaster.

The cuts are instructive, if the strata are differently coloured.

If we mark certain points in the originally level strata, or if we divide the whole system into cubes, we may study the locomotion and deformation of every point, line, square, or cube of our system; the vertical, as well as the horizontal component of displacement, may be observed and measured.

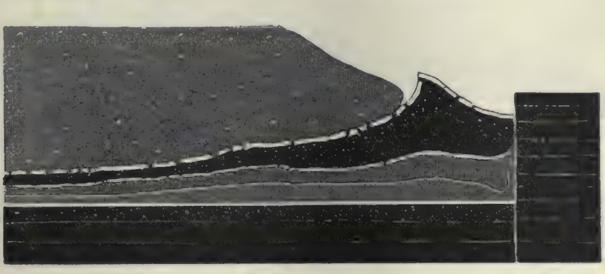

FIG. 1.

The following experiments explain some points in th theoretical essay:—

The plastic sediments are loaded by a mass, and get deformed in the manner illustrated by Fig. 1. The black base and the black side-wall at the right hand (fault scarp) are rigid; the plastic strata are pushed up in form of a fold; the highest white stratum is rigid, and gets torn into clods.

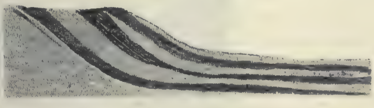

FIG. 2.

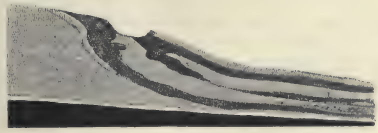

FIG. 3.

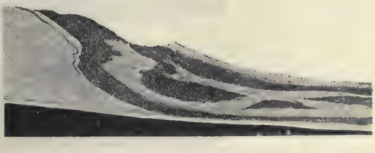

FIG. 4.

Figs. 2–4 show successive stages. A delta, deposited under water, gets elevated, it emerges; the masses are shaken slightly and glide over the inclined base. Folding succeeds, as Figs. 3 and 4 show.

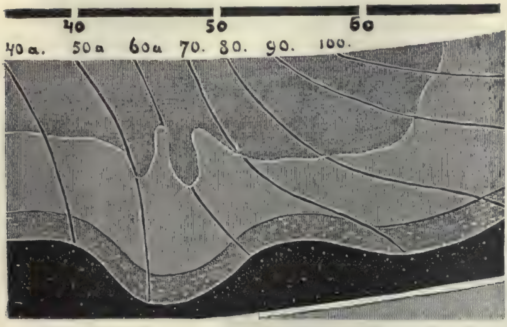

Fig. 5.

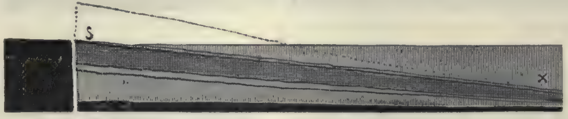
In Fig. 5 the strata, gliding over the inclined plane to the left, were divided by vertical lines. Distance of lines = 0·1 metre. At the top of the figure the fixed scale is noted. Point 40*a* of the strata originally lay directly below the scale-point 40, 60*a* was placed below 60, and so on.

We see at once the amount of horizontal (gliding) movement. The vertical lines are deformed in the direction of the motion. The parts near the base move little, the parts near the surface have a higher velocity, so that the vertical lines of division get curved. The motion being intense in the highland (at the right hand), the vertical lines in this region are pushed over and assume a flat position.

The surface of the gliding masses in this case remained level, as the material was very plastic; yet folding in the depth of the masses is remarkable. We see that a fold chain may have a wide surface; the intensely folded regions get exposed only after an extensive erosion or abrasion occurred. This experiment shows also how the motion and the amount of folding decrease in the direction towards the base.

Figs. 6 and 7 illustrate my conception of the process of glide-folding as it occurs in nature. The black parts form the solid basement; at S we observe a fault scarp (the coast of a continent). In the sea the sediments SX are deposited. Warming of the newly-deposited masses, and of the lower parts of the earth's crust, in course of time elevates the sediments, as the dotted line in Fig. 6 notes. The sediments glide over the inclined plane towards the right, and form a fold-chain, O.

The motion of a single point is noted in Fig. 8. Point S first gets elevated (through thermal intumescence) to S', and then it glides towards S''. In most cases the way described by a point is complicated, as Fig. 9 illustrates. Elevation having reached a certain degree, the masses glide a little, elevation continues, again gliding succeeds, and so on.



ig. 6.

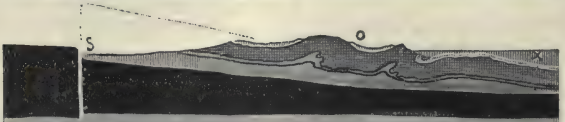


Fig. 7.

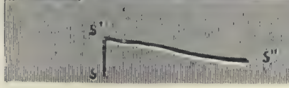

Fig. 8.

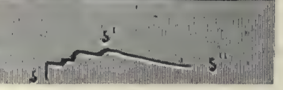

Fig. 9.

The highland in the back of the fold-chain (black mass at the left hand) gets eroded; cooling causes a subsidence of this region, the earth's crust breaks, and through the fissures and faults, in many cases, eruptive material escapes. A volcanic chain is built up in the back of the fold-chain (Fig. 10). In course of time the fold-chain

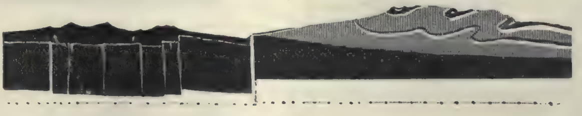

Fig. 10.

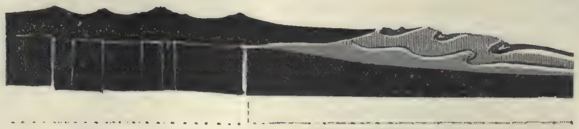

Fig. 11.

may be covered partly by the volcanic chain (Fig. 11). Fig. 12 (profile), and Fig. 13 (surface of the same experiment) show that pulling (tearing) and pushing (folding) are *reciprocal processes*. The strata, gliding away from the highland, are torn in this district, whereas compression and folding occur in the lowland.

The surface of the strata (Fig. 13) was divided into squares of different colour (like a chess-board), so that we may see and measure directly the direction and amount of pushing and pulling in both districts. Black fissures occur at the left hand, grey folds at the right hand.

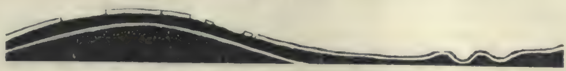

FIG. 12.

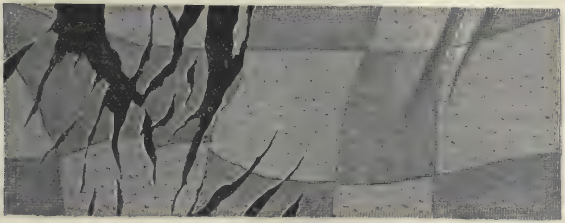

FIG. 13.

The base in this, as in the other cases, was rigid; there occurred *no compression in the depth*, yet folding succeeded in the gliding strata.

Folding, according to my opinion, does not depend on a contraction of our planet, but is a simple gliding phenomenon.

E. REYER.

NOTES.

AT the meeting of Section A of the British Association on Monday, August 8, there will be a discussion on the subject of a National Physical Laboratory. The discussion will be opened by Prof. Oliver J. Lodge, F.R.S.

THE Academy of Sciences at Berlin has conferred upon Lord Kelvin one of the first four Helmholtz gold medals.

THE French Association for the Advancement of Science will hold its twenty-first meeting at Pau from September 15 to 22.

THE Council of University College have accepted a tender for the erection of new technical laboratories for the practical teaching of mechanical and electrical engineering. Care has been taken that the buildings shall accord with all the conditions of modern teaching, but of course it is necessary that provision shall also be made for an adequate supply of apparatus and plant. The part of the proposed laboratory which is to be set apart for electrical engineering cannot be properly fitted up for a sum of less than £2010, and Prof. Fleming has issued an appeal to all who may be able and willing to help him in obtaining this amount. In the course of his appeal he says: "The Council do not at present see their way to incur this additional expenditure over and above the cost of the buildings, and yet it is absolutely essential to the completion of the project. The Council have, therefore, by a minute of their proceedings of May 7, 1892, recommended this very essential part of the proposed work to the notice and liberality of those who may be disposed to help. Thus sanctioned and authorized by the Council, the Professor of Electrical Engineering begs permission to bring under your notice the necessity for a special Electrical Apparatus Fund, and desires to invite your aid in the formation of such a fund of £2010, to be entitled 'The University College Electrical Engineering Apparatus Fund.'" Prof. Fleming is anxious that the sum should, if possible, be obtained within the next six months. Donations should be sent to the Secretary of University College, marked "Electrical Apparatus Fund."

THE services rendered by the late Sir William Macleay to the Linnean Society of New South Wales and to science in general are to be commemorated by the publication of a memorial volume. This was decided recently at a general meeting of the New South Wales Linnean Society. It is proposed that, in addition to a portrait and memoir of Sir William Macleay, the volume shall consist of original papers on those branches of science in the advancement of which he was especially interested—zoology, ethnology, botany, and geology. Promises of papers have already been received from Sir F. von Mueller, Prof. Hutton, Prof. J. Parker, Prof. Baldwin Spencer, and other leading Australian biologists. It is intended that, as regards "style of get up and illustration," the volume shall be fully worthy of the occasion. The expense is to be met by means of a public subscription. Every ordinary member of the Society subscribing one guinea or upwards, and any non-member subscribing two guineas or upwards, to the memorial will receive a copy of the volume. At the meeting of the Society on May 25, the President announced that a number of subscriptions had been received in answer to a circular issued a few weeks previously. It was necessary, however, he said, that a considerably larger sum should be collected before the Council would be in a position to proceed with the work.

THE Governors of the Merchant Venturers' School, Bristol, have elected to the vacant Lectureship in Biology Mr. G. P. Darnell-Smith, B.Sc., assistant to Dr. W. Marcet at University College, London. Mr. Smith is a student of University College, and graduated with honours in botany and zoology in 1891.

THE thunderstorms which we referred to in our last issue gave a very decided, but temporary, check to the temperature, the highest day readings falling about 20° after the storm; and the heavy rains which accompanied the disturbed weather have materially lessened the deficiency of rainfall, which has been so characteristic a feature for some months past. By the end of last week the temperature had recovered, and the weather became very fine in the southern parts of the kingdom, the maxima reaching from 80° to 85° at some inland stations on Sunday; while conditions remained unsettled, with heavy rain, in the north and west, owing to a cyclonic area which passed along the Irish coast, and caused a thunderstorm on the east coast. During the last day or two, depressions have passed to the northward of our islands, again causing unsettled weather, with rain in most parts; while the westerly winds have increased considerably in strength, reaching the force of a gale on our north-west coasts.

The *Weekly Weather Report* issued on the 2nd instant shows that the rainfall differed very considerably in various parts; in most of England, the north and west of Scotland, and in Ireland, the amount exceeded the mean. The greatest deficiency on the amount due from the beginning of the year is over the midland, south, and south-west of England, and the west of Scotland, the amounts varying from about 3 to 7 inches. Bright sunshine exceeded the average amount for the week, except in the north-western and south-western districts.

The Washington Weather Bureau has recently issued a report on its work for the last six months of the year 1891, dealing more with the scientific and practical work of the Department than with the administrative duties, which were referred to in a special report issued in October last (Nature, vol. xlv. p. 86). Prof. Harrington states that an endeavour has been made to improve the weather forecasts in every possible way; the time covered by the forecasts has been extended to thirty-six hours, and longer in some cases. Every effort is made to distribute the information as widely as possible, and for this purpose the telephone is becoming more popular, and will possibly eventually supersede the telegraph. Increased interest has of late been manifested in regard to meteorological education in the United States, and a list is given of the institutions which announce definite courses of instruction. A very large accumulation of data is now in the possession of the Weather Bureau; a summary of these, under each element, is given in the report, and it is proposed to utilize the materials by special studies to be undertaken by the officers of the Bureau. The study of terrestrial magnetism in connection with meteorology, with the object of discovering some physical relations connecting them, has from time to time been made by various persons, but, on the whole, it has not led to definite results. Prof. Harrington states, however, that the subject is now being specially investigated by Prof. F. H. Bigelow, one of the meteorologists of the Bureau, and that such progress has been made as to render it quite certain that they are intimately associated. By the method of analysis now being used by Prof. Bigelow, which differs from that hitherto employed, it is stated that he has been able to disentangle several of the magnetic fields surrounding the earth, which are observed in the magnetic curves as an integrated effect.

According to the *Pioneer Mail*, the Port Officer of Mangalore reports that a native craft was overtaken by heavy weather and made for Mangalore, where there is a bad bar with about eight feet of water in it. A tremendous sea was breaking over the bar, so, before crossing it, and while running in, the native skipper opened one oil cask, forming a part of the cargo, and scattered it all round in the sea plentifully, with the result that he took his craft across the bar safely, and so saved the vessel and the cargo. The vessel's name was *Mahadeprasad*, and she was of 95 tons, bound from Cochin to Bombay. This is said to be the first case on record of a native tindal who has successfully used the oil in troubled waters.

Mr. H. Rowland-Brown, writing in the current number of the *Entomologist*, says that when sitting in the Temple Gardens on June 22 he saw a fine male *Colias edusa* fly across the lawn. The excitement among the sparrows was "simply immense," but the butterfly "proved a match for his innumerable pursuers, and sailed calmly over the railings towards the City." The editor of the *Entomologist* adds a note to the effect that this species was seen in London in 1877, which is remembered as the great "*edusa* year."

A fact noted in the current number of the *Zoologist* gives a very vivid idea of the depth of snow and drift in the north of Scotland last winter. In the parish of Lairg, a month or two after the first thaw set in, two full-grown stags were found dead in a hollow in a "burn." The first thing one of the keepers saw was a stag's antlers above the snow. These he took for the branch of a tree, but on going near he found that a stag had been smothered by the drifting snow while standing on its feet. A week or so afterwards, when more of the snow was melted, another stag was discovered. This one had been smothered while lying down. He was close to his comrade.

The Peabody Museum has issued, in its series of archæological and ethnological papers, an interesting report on pile-structures in Naaman's Creek, near Claymont, Delaware, by Dr. H. T. Cresson. These pile-structures are believed to be remains of prehistoric fish-weirs.

The Chicago Exhibition will include what promises to be a very important department for the exhibition of objects relating to ethnology, archæology, history, and cartography. A special bureau connected with the department will represent the history of the Latin-American Republics, and include all relics of the time of Columbus. There will also be a group of "isolated and collective exhibits." A full account of the plan of the department, and of the classification of the exhibits, has been prepared by Mr. F. W. Putnam, chief of the department. By means of special research in different parts of America, under Mr. Putnam's direction, important scientific collections in the ethnological and archæological sections will be brought together. It is hoped that every State Board and many historical and scientific Societies, as well as owners of private collections, will do what they can to contribute to the success of the department, so that it may present a full and effective illustration of the present status of American archæology and ethnology.

Messrs. Mitchell and Hughes have issued the Transactions of the County of Middlesex Natural History and Science Society for the sessions 1889–90 and 1890–91. The volume contains papers on rabies—its natural history and the means of extinguishing it, by Arthur Nicols; the best means of examining Rotifers under the microscope, by C. Rousselet; the tubercle bacillus, by A. W. Williams; and "A Night among the Infinities," with a description of the instruments at Stanmore Observatory, by Sydney T. Klein.

The July number of *Natural Science* opens with some "Notes and Comments," and contains articles on "The Story of Olenellus," by Prof. G. A. J. Cole; the physical features of the Norfolk Broads, by J. W. Gregory; the evolution of flat-fish, by Prof. A. Giard; is Stigmaria a root or a rhizome? by T. Hick (with "A Reply," by Prof. W. C. Williamson, F.R.S., and "A Rejoinder," by T. Hick); agricultural museums, by J. H. Crawford; and amber and fossil plants, by A. C. Seward.

A paper on three deep wells in Manitoba, by Mr. J. B. Tyrrell, was lately submitted to the Royal Society of Canada, and has now been printed in the Transactions. It contains a good deal of interesting and well arranged geological information.

Mr. D. J. Macgowan, writing in the *Shanghai Mercury*, gives an account of some remarkable statements made by a group of Chinese traders who lately undertook a mercantile exploration of the interior of Southern Formosa. They started from Lamalan, which Mr. Macgowan takes to be Chockeday of the charts, and in seven days reached their objective point, Hualin Stream. They lodged in stone caverns, and the chattering of monkeys and the sounds of insects seemed to them "appalling and indescribable." The region was so "weird" that it reminded them of "legends of the kingdom of hobgoblins." Among the trees were some of "prodigious girth, forming a vast forest." These trees are said to measure more than ten outstretched arms. A tree said to flourish in the same forest is described as bearing "flowers, red and white, which are larger than a sieve, and of extraordinary fragrance." Mr. Macgowan adds:—"Mr. Taylor, while searching for orchids, heard of these majestic trees and huge flowers, which he inferred, from what natives said, were epiphyte orchids. I am moved to make known this sylvan discovery in the hope that, pending the exploration of this *terra incognita* by our botanists, Dr. Henry or Mr. Ford, residents in Formosa, will take measures to provide those naturalists with specimens of flowers, seeds, leaves, and bark of the trees concerning which the Chinese have excited our curiosity."

IN a capital address on "tooth culture," delivered at the annual meeting of the Eastern Counties Branch of the British Dental Association, and printed in the current number of the *Lancet*, Sir James Crichton-Browne referred to a change which has taken place in bread, as one of the causes of the increase of dental caries. So far as our own country is concerned, this is essentially an age of white bread and fine flour, and it is an age therefore in which we are no longer partaking, to anything like the same amount that our ancestors did, of the bran or husky parts of wheat, and so are deprived to a large degree of a chemical element which they contain—namely, fluorine. The late Dr. George Wilson showed that fluorine is more widely distributed in nature than was before his time supposed, but still, as he pointed out, it is but sparingly present where it does occur, and the only channels by which it can apparently find its way into the animal economy are through the siliceous stems of grasses and the outer husks of grain, in which it exists in comparative abundance. Analysis has proved that the enamel of the teeth contains more fluorine, in the form of fluoride of calcium, than any other part of the body, and fluorine might, indeed, be regarded as the characteristic chemical constituent of this structure, the hardest of all animal tissue, and containing 95·5 per per cent. of salts, against 72 per cent. in the dentine. As this is so, it is clear that a supply of fluorine, while the development of the teeth is proceeding, is essential to the proper formation of the enamel, and that any deficiency in this respect must result in thin and inferior enamel. Sir James Crichton-Browne thinks it well worthy of consideration whether the reintroduction into our diet of a supply of fluorine in some suitable natural form—and what form, he asks, can be more suitable than that in which it exists in the pellicles of our grain stuffs?—might not do something to fortify the teeth of the next generation.

THE recent publication is announced of the first number of a new monthly journal under the title *Rivista di patologia vegetale*. It is edited by Sigg. A. N. and A. Berlese, and published at Avellino, in Italy; and is to be devoted to the study of animal and vegetable parasites infesting cultivated plants, to the diseases which they cause, and the remedies employed to combat them.

DR. H. C. CHAPMAN contributes to the latest instalment of the Proceedings of the Academy of Natural Sciences, Philadelphia, a paper describing observations on the brain of the gorilla. He says that while the fissures and convolutions are disposed in the brain of the gorilla in the same manner, generally speaking, as in that of man or of the chimpanzee or orang, it is nevertheless a low type of brain, being much less convoluted than the brain of man or of either of the two other anthropoids. If it were permissible, in the absence of living links or sufficient fossil remains, to speculate upon the development of man and the anthropoids from lower forms of simian life, Dr. Chapman thinks it might be inferred from the character of the brain that the gorilla had descended from some extinct *Cynocephalus*; the chimpanzee and orang from extinct macaque and gibbon-like forms; and man from some generalized simian form combining in itself the characteristics of existing anthropoids.

AT the annual meeting of the Department of Electricity of the Brooklyn Institute of Arts and Sciences on June 1, Prof. E. J. Houston delivered a lecture on recent advances in the applications of electricity. Turning for a moment from the past to the future, Prof. Houston said it was related of Faraday that when asked his opinion of the future of the electric motor, he put up his cane and stopped it. That was Faraday's opinion. Prof. Houston's view was more favourable. The true efficiency of a triple expansion steam engine, he said, did not exceed 17 per cent. as a maximum. With the electric motor we could already get an efficiency of from 90 to 95 per cent., but it was to-day dependent on the steam-engine. A cheaper method would be devised for generating currents, and he believed there were now those living who would see the steam-engine relegated to the scrap heap. Possibly the motor of the future would be operated by thermo-electricity. Possibly a means would be devised of converting the latent energy of coal directly into potential electrical energy. He believed in the successful solution of the problem of aërial navigation in the near future. He was confident that ere long our present methods of electric illumination, in which 97 to 98 per cent. of the energy was expended in useless heat rays, would be supplanted by one in which the order was reversed—in which 97 to 98 per cent. would be converted into light, and but 2 to 3 into heat. And finally, he believed the time was near at hand when electro-therapeutists, instead of regarding the human body as a vehicle for electricity, would regard it as a source of electricity. They would then make their diagnoses with the voltmeter, the ammeter, and the condenser, and the result would then be definite, instead of, as at present, "hit or miss."

THE *Mediterranean Naturalist* quotes a statement made by the late Rev. H. Seddall, who was many years a resident of Malta, as to a curious form of industry formerly practised by the Maltese. "Five species of *Pinna*," wrote Mr. Seddall, "are found in Malta, some of them common in the harbours within reach of a boat or a pole hook. They project from the mud amongst the Zostera roots, to which they are attached by their silken cable. Of this silk, which is of fine texture, but heavy, I have seen gloves made."

THE additions to the Zoological Society's Gardens during the past week include a Palm Squirrel (*Sciurus palmarum*) from India, presented by Miss Daisy Fox; a Common Roe (*Capreolus capræa* ♂), European, presented by Mr. E. J. H. Towers; a Tawny Owl (*Syrnium aluco*), European, presented by Mr. Leigh Robinson; a Bronze Fruit Pigeon (*Carpophaga ænea*) from India, presented by Mr. J. L. Shand; a Tuberculated Tortoise (*Homopus femoralis*), a Tent Tortoise (*Testudo tentoria*), two Fisk's Tortoises (*Testudo fiski*), a Robben Island Snake (*Coronella phocarum*) from South Africa, presented by the Rev. G. H. R. Fisk, C.M.Z.S.; two Green Lizards (*Lacerta viridis*), European, three Viperine Snakes (*Tropidonotus viperinus*) from North Africa, presented by the Rev. F. M. Haines; a Common Chameleon (*Chamæleon vulgaris*) from North Africa, presented by Mr. Samuel L. Bensusan; a Water Viper (*Cenchris piscivora*) from North America, presented by Mr. Ernest Brewerton; a —— Zorilla (*Zorilla typica*), a Grey Monitor (*Varanus griseus*) from Egypt, a Stanley Parrakeet (*Platycercus icterotis*) from Australia, deposited; two Asiatic Wild Asses (*Equus onager* ♂ ♀) from South-west Asia, received in exchange; four Wapiti Deer (*Cervus canadensis* ♂ ♀ ♀ ♀) born in the Gardens.

OUR ASTRONOMICAL COLUMN.

THE RED SPOT ON JUPITER.—M. J. J. Landerer, in *Bulletin Astronomique* (tome ix., June), gives the results of his measurements of the dimensions and Jovicentric latitude of the red spot on Jupiter. The method he adopted was to make use of the transit of the satellite's shadows as they were projected on the extreme points of the two axes of the spot, the mean giving the position of the spot's centre. In the case of the third satellite, when its latitude was −1° 45′ 14″, that of its shadow—reckoning from the bottom side of the spot—was −30° 34′ 36″. The latitude of the shadow of the second satellite came out to be −17° 48′ 10″, and after allowing for the fact that it was projected tangentially on the side of the spot and for the diffraction of the instrument, this value for the latitude of the north side of the spot became −20° 56′ 37″. Taking the mean of the values obtained from both satellites, the latitude of the centre was −25° 45′ 36″, and, with the polar semi-diameter as unity, the magnitude of the spot was 0·20297.

The mean value of the latitude obtained from eleven observations by Denning, Green, Ricco, Williams, Keeler, and Terby was 21°·5 ± 2°·05, the major and minor axes of the spot being 0·555 and 0·188 respectively. Using the micrometer, the latitude, according to Young, amounted to 40°; while Denning estimated that the major axis embraced an arc varying between 29°·3 and 37°·8.

A Mean Time Sun-dial.—A very ingenious sun-dial, capable of indicating mean time, has been recently invented by Major-General Oliver, the construction of the instrument being undertaken by Messrs. Negretti and Zambra. In an ordinary sun-dial, the time is read off generally by the position of the centre of a shadow, cast by a straight-edged style, on a flat surface on which the hours are graduated. The peculiarity of the present instrument is that the time is indicated by the position of the *edge* of a shadow cast by a "nine-pin" shaped style, with regard to an equatorial circular line. The style is fixed along the diameter of a semicircular arc, which is clamped by means of a screw to a firm stand to suit any latitude; at right angles to this arc, and also capable of adjustment, is another semicircle, graduated in five-minute divisions. Owing to the change of declination of the sun throughout the year, different *parts* of the shadow of the style are brought on to the hour circle in such a way that the difference between the time indicated (by the dial) and mean time, or the equation of time, is counterbalanced by the change in position of the shadow, due to the peculiar form of the style. If we start, for instance, on December 24, the readings have to be taken from the shadow of the eastern edge of the lower part of the style in an upward direction, the bulging out of the style counteracting the increase and decrease of the equation of time (which is here positive) until June 14 is reached. Owing to the thickness of the style's axis, a slight adjustment is here necessary when we pass to the other side of the style; this adjustment is facilitated by placing the twelve o'clock graduation to the western of two marks shown on the vertical circle. This being done, the readings from the shadow, cast now by the western side of the upper protuberance, are taken until the other nodal point on June 14 is reached. At this time also—in fact, four times a year—this slight alteration has to be made. From this latter date until December 24 is reached the same process is repeated, only the respective opposite sides of the style are used in the inverse order. To obviate the necessity of having two styles, which, of course, would have to be the case if the greatest accuracy were desired, owing to the differences in the maximum values of the equation of time, one with a mean contour is given: the error produced by this is practically very slight, amounting in time to about one-sixteenth of greatest value of the equation of time—a quantity scarcely appreciable, on account of the lack of sharpness of the edge of the shadow.

Comet Swift (1892 March 6).—*Edinburgh Circular* No. 28 contains a continuation of the ephemeris of Comet Swift (March 6, 1892) for the month of July and part of August, from which we make the following extract:—

Berlin Midnight.

1892.	R.A.	Decl.	log Δ.	log *r*.	Br
	h. m. s	° ′			
July 7	0 52 36	+48 0·5			
8	53 33	12·6	0·2391	0·2552	0·17
9	54 28	24·5			
10	55 20	36·2			
11	56 10	47·7			
12	56 58	59·0	0·2427	0·2665	0·16
13	57 43	49 10·0			

The brightness at the time of discovery being taken as the unit of brightness, it will be seen that the comet is at present more than five times dimmer than it was in March. In fact, it is rapidly becoming invisible, and will only be able to be observed with large instruments for another two months or so. Its position on July 7 will lie to the very southern extremity of the constellation of Cassiopeia, forming nearly an equilateral triangle with ξ and π.

Stars' Proper Motions.—Mr. J. G. Porter contributes to the *Astronomical Journal*, No. 268, a catalogue of the proper motions of 301 stars, which amount to half a second or more in a year. This list, as he informs us, is from a still more extensive catalogue which he hopes soon to publish; and the proper motions contained in it are rendered more trustworthy by the enlightenment of new observations. The positions of the stars are all brought up to the epoch 1900·0.

GEOGRAPHICAL NOTES.

M. Charles Allnand describes his researches on the Island of Mahé, the largest of the Seychelles Group (see Nature, p. 162), in a letter to the Paris Geographical Society. He has studied the fauna with some care, and remarks on the singular poverty of animal life compared with the great luxuriance of vegetation. In Port Victoria, the chief settlement in Mahé, the only form of butcher-meat obtainable is the flesh of the great turtle (*Chelone midas*) whose shell is valueless, the tortoise-shell fisheries of the island depending on the *Chelone imbricata*. M. Allnand hopes to bring back with him living specimens of the elephantine turtles of the Aldabra Islands, specimens of which have been transported to the Seychelles.

The expectation of an Antarctic expedition, on which valuable scientific observations might have been made, has proved illusory. Captain Gray, of Peterhead, had organized a whaling voyage to the far south, and appealed to the public for funds to carry it out with some prospect of commercial success, but the response was so unsatisfactory that the enterprise has been abandoned. From a scientific point of view, the advantages of Antarctic exploration is so great, and the probability of valuable practical results so apparent, that the apathy alike of the British and Australian Governments as well as of the general geographical public is incomprehensible. The fact that no steamer has ever been despatched to the south of the Antarctic Circle with the object of attaining high latitudes says much for the prudence and little for the energy of present-day explorers.

A Chair of Colonial Geography is about to be established at the Sorbonne for the special study of the French colonies.

The discovery of America by Columbus is to be celebrated in Hamburg on October 11 and 12 by gatherings of delegates from the German Universities and Geographical Societies, by whom papers bearing on German enterprise in the sixteenth century will be read. An exhibition of articles illustrating the early connection of Hamburg and America will also be held.

The Manchester Geographical Society has just published its *Journal* for July–September 1891, containing several interesting papers on India and a variety of short notices. It is unfortunate that the small local encouragement given to this Society makes the earlier publication of its memoirs possible. Surely Manchester could afford and should endeavour to maintain a Geographical Society as prosperous financially as it is enterprising and persevering. The contrast between the many provincial Geographical Societies in Germany and France with the three already established in England corresponds to the relative interest in geography as an aid to commerce on the Continent and in Great Britain.

METALLIC CARBONYLS.[1]

Justus Liebig, perhaps the most prophetic mind among modern men of science, wrote in the year 1834 in the *Annalen der Pharmacie*. "I have previously announced that carbonic oxide may be considered as a radical, of which carbonic acid and oxalic acid are the oxides, and phosgene gas is the chloride. The further pursuit of this idea has led me to the most singular and the most remarkable results."

Liebig has not told us what these results were, and it has taken many years before the progress of chemical research has revealed to us what may at that early date have been before Liebig's vision. I will to-night bring before you some important discoveries made only within the last few years by following up Liebig's idea.

---

[1] Friday Evening Discourse delivered at the Royal Institution by Ludwig Mond, F.R.S., on June 3.

Carbonic oxide, composed of one atom of carbon and one atom of oxygen, is a colourless gas, without taste or smell, which I have here in this jar. It burns with a blue flame. When it acts as a radical combining with other bodies, we term it carbonyl, and its compounds with other elements or radicals are termed carbonyls.

Liebig defined a radical as a compound having the characteristics of a simple body, which would combine with, replace, and be replaced by simple bodies. In more modern times a radical has been defined as an unsatiated body. I am of course speaking of chemical radicals. If we look at it from the modern point of view, carbonyl should be the very model of a radical, because only half of the four valencies of the carbon atom are satiated, the other two remaining free. Carbonic oxide should even be a most violent radical, because, amongst all organic radicals, it is the only one we know to exist in the atomic or free state. All the other organic radicals, even such typical ones as cyanogen and acetylene, are known to us as molecules composed of two atoms of the radical, so that the cyanogen gas and acetylene gas we know should more properly be called di-cyanogen and di-acetylene; they consist of two atoms of the radical cyanogen or of the radical acetylene, the free valencies or combining powers of which satiate or neutralize each other. On the other hand, carbonic oxide gas, as I stated before, makes the sole exception. Its molecule contains only one atom of carbonyl moving about with its free valencies unfettered by a second atom. For all that, carbonic oxide is by no means a violent body, but the very reverse, and instead of being ready to attack with its two free valencies anything coming in its way, until very recently we only knew it to interact and to combine with substances possessing themselves extreme attacking powers, such as chlorine and potassium. Although Liebig had so long ago proclaimed it as a radical, the chemical world was startled when, two years ago, I announced in a paper I communicated to the Chemical Society in conjunction with Drs. Langer and Quincke, that carbonic oxide combines at ordinary temperature with so inactive an element as nickel, and forms a well-defined compound of very peculiar properties.

The fact that carbonic oxide does not possess the chemical activity one would suppose in a radical composed of single atoms may, I believe, be explained by assuming that the two valencies of carbon which are not combined with oxygen do satiate or neutralize each other. Everybody admits that the valencies of two different carbon atoms, which are all considered of equal value, can neutralize each other. I see, therefore, no reason to question the possibility of two valencies of the same carbon atom neutralizing each other. On this assumption carbonic oxide may be looked upon as a self-satisfied body—one which keeps in check its free affinities within itself.

You have here the typical carbon radicals containing one atom of that element, acetylene, methylene, methyl, cyanogen, and carbonyl. In the second column you have these substances as they are known to us in the free state. You see the carbonyl is the only one which exists in the free state as a single atom, while all the others only exist as molecules, composed of two atoms the free valencies of which neutralize each other. The carbonyl I have represented in the last formula, with the two valencies not combined with oxygen neutralizing each other, so that in this way it also becomes a satiated body. I will try to make this still plainer to you by means of the models I have before me.

The paper published by Liebig in 1834, from which I have already quoted, was entitled "On the Action of Carbonic Oxide on Potassium." In it Liebig fully described the preparation and properties of the first metallic carbonyl known—a compound of potassium and carbonic oxide. Liebig obtained this compound by the direct action of carbonic oxide upon potassium at a temperature of 80° C., and proved it to be identical with a substance which had been previously obtained as a very disagreeable by-product of the manufacture of potassium from potash and carbon by Brunner's method. It forms a grey powder which is not volatile, and which on treatment with water yields a red solution, gradually turning yellow in contact with air, and from which on evaporation a yellow salt is obtained, called potassium croconate, on account of its colour. Liebig showed this salt to consist of two atoms of potassium, five of carbon, and five of oxygen, and not to contain any hydrogen, as had previously been supposed.

Since the publication of Liebig's paper, potassium carbonyl has been studied by numerous investigators, amongst whom Sir Benjamin Brodie deserves particular mention; but it has been reserved to Nietzki and Benkiser to determine finally in the year 1885, by a series of brilliant investigations, its exact constitution, and its place in the edifice of chemistry. They have proved that it has the formula $K_6C_6O_6$; that the six carbons in this compound are linked together in the form of a benzole ring; that, in fact, the compound is hexhydroxylbenzole, in which all the hydrogen is replaced by potassium. By simple treatment with an acid it can be converted into the hexhydroxylbenzole, and from this substance it is possible to produce, by a series of reactions well known to organic chemists, the whole wide range of the benzole compounds. The body which Liebig obtained by the direct action of carbonic oxide on potassium has thus enabled us to prepare synthetically in a very simple way from purely inorganic substances—to wit, from potash and carbon, or if we like even from potash and iron—the whole series of those most important and interesting compounds called aromatic compounds, including all the coal-tar colours, which have furnished us with an undreamt-of variety of innumerable hues and shades of colour, as well as many new substances of great value to suffering humanity as medicines. Surely a startling result, which alone would have fully justified Liebig's prediction of 1834!

Speaking of coal-tar colours, everybody will be reminded of the great loss the scientific world has recently sustained by the death of August Wilhelm Hofmann, their first discoverer, Liebig's greatest pupil. Hofmann will ever be remembered in this Institution, where he so often delighted the audience by his lucid lectures, and in whose welfare he took the greatest interest, of which he gave us a fresh proof only last year, in the charming letter he wrote on the occasion of his election as an honorary member.

Looking back upon the wonderful outcome of Liebig's idea I have referred to, it seems surprising indeed that others should not have followed up his work by attempting to obtain other metallic carbonyls.

A very few experiments were made with other alkaline metals: sodium, otherwise resembling potassium so closely, has been shown not to combine with carbonic oxide; lithium and cæsium are stated to behave similarly to potassium. But metals of other groups received little or no attention. The very important *rôle* which carbonic oxide plays in the manufacture of iron did lead a number of metallurgists (among whom Sir Lowthian Bell and Dr. Alder Wright are the most prominent) to study its action upon metallic iron and other heavy metals, including nickel and cobalt at high temperatures. They proved that these metals have the property to split up carbonic oxide into carbon and carbonic acid at a low red heat, a result of great importance, which threw a new light upon the chemistry of the blast furnace. None of these investigators, however, turned their attention to obtaining compounds of these metals with carbonic oxide, and, owing to the high temperature and the other conditions under which they worked, the existence of such compounds could not come under their observation. In order to obtain these compounds, very special conditions must be observed, which are fully described in the papers I have published during the last two years in conjunction with Dr. Langer and Dr. Quincke.

The metals must be prepared with great care, so as to obtain them in an extremely fine state of division, and must be treated with carbonic oxide at a *low temperature*. The best results are obtained when the oxalate of the metal is heated in a current of hydrogen at the lowest temperature at which its reduction to the metallic state is possible. I have in the tube before me metallic nickel prepared in this way, and over which a slow current of carbonic oxide is now passing; the carbonic oxide before entering the tube burns, as you see, with a blue non-luminous flame. After passing over the nickel it burns with a highly luminous flame, which is due to the separation of metallic nickel from the nickel carbonyl formed in the tube, which is heated to incandescence in the flame. (In passing the gas issuing from our tube through a glass tube heated to about 200°, we obtain a metallic mirror of pure nickel, because at this temperature the nickel carbonyl is again completely resolved into its components, nickel and carbonic oxide. If we pass the gas through a freezing mixture, you will observe that a colourless liquid is condensed, of which I have a larger quantity standing in this tube. This liquid formed is pure nickel carbonyl, and has the formula $Ni(CO)_4$.

If cooled to $-25°$ C., it solidifies, forming needle-shaped crystals. The vapour of nickel carbonyl possesses a characteristic odour and is poisonous, but not more so than carbonic oxide gas. Prof. McKendrick has studied the physiological action of this liquid, and has found that, when injected subcutaneously in extremely small doses in rabbits, it produces an extraordinary reduction in temperature, in some cases as much as 12°.

The liquid can be completely distilled without decomposition, but from its solution in liquids of a higher boiling-point it cannot be obtained by rectification. On heating such a solution the compound is decomposed, nickel being separated in the liquid, while carbonic oxide gas escapes. I will try to demonstrate this by an experiment.

We have here a solution of the substance in heavy petroleum oil, which you will, in a few minutes, see turns completely black on heating by the separation of nickel, while a gas escapes which is carbonic oxide.

In a similar way, when the nickel carbonyl is attacked by oxidizing agents, such as nitric acid, chlorine, or bromine, it is readily broken up, nickel salts being formed, and carbonic oxide being liberated. Sulphur acts in a similar way. Metals, even potassium, alkalies, and acids, which have no oxidizing power, will not act upon the liquid at all, nor do the salts of other metals react upon it. The substance behaves therefore, chemically, in an entirely different manner from potassium carbonyl, and does not lead, as the other does, by easy methods to complicated organic compounds. It does not show any one of the reactions which are so characteristic for organic bodies containing carbonyl, such as the ketones and quinones; and we have not been able, in spite of very numerous experiments, either to substitute the carbonic oxide in this compound by other bivalent groups, or to introduce the carbonic oxide by means of this compound into organic substances.

By exposing the liquid to atmospheric air, a precipitate of carbonate of nickel is slowly formed of varying composition, which is yellowish-white if perfectly dry air is used, and varies from a light green to a brownish colour if more or less moisture is present. We have found all these precipitates to dissolve easily and completely in dilute acid, with evolution of carbonic acid, leaving ordinary nickel salts behind, and can therefore not agree with the view propounded by Prof. Berthelot, in a communication to the French Academy of Sciences, that these precipitates contain a compound of nickel with carbon and oxygen, comparable to the so-called oxides of organo-metallic compounds. In the same paper Prof. Berthelot has described a beautiful reaction of nickel carbonyl with nitric oxide, which we will now show you. You will notice the intense blue coloration which the liquid solution of nickel carbonyl in alcohol assumes by passing the nitric oxide through it. Prof. Berthelot has reserved to himself the study of this interesting body, but has so far not published anything further about it.

The chemical properties of the compound I have just described to you are without parallel; we do not know a single substance of similar properties. It became, therefore, of special interest to study the physical properties of the compound.

Prof. Quincke, of Heidelberg, has kindly determined its magnetic properties, and found that it possesses in a high degree the property discovered by Faraday, and called by him diamagnetism, which is the more remarkable, as all the other nickel compounds are paramagnetic. He also found that it is an almost perfect non-conductor of electricity, in this respect differing from all other nickel compounds.

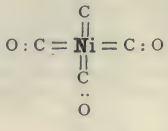
The absorption spectrum, and also the flame spectrum, of our compound are at present under investigation by those indefatigable spectroscopists, Profs. Dewar and Liveing, by whose kindness I am enabled to bring before you, in advance of a paper they are sending to the Royal Society, some of the interesting results they have obtained. We have here a photograph of the absorption spectrum, obtained by means of a hollow prism through quartz plates filled with nickel carbonyl, through which the spark spectrum of iron is passed, which is photographed on the same plate. You see that the whole of the ultra-violet rays of the iron spectrum have disappeared, being completely absorbed by the nickel carbonyl, which is thus quite opaque for all the rays beyond the wave-length 3820. The spectrum of the highly luminous flame of nickel carbonyl, which I have shown you before, is quite continuous; but if the nickel carbonyl is diluted with hydrogen, and the mixture burnt by means of oxygen, the gases burn with a bright yellowish-green flame without visible smoke; and the spectrum of this flame shows in its visible part, on a background of a continuous spectrum, a large number of bands, brightest in the green, but extending on the red side beyond the red line of lithium, and on the violet side well into the blue. These bands cannot be seen on the photograph which I will now show you, the visible part of the spectrum appearing continuous; but beyond the visible part the photograph shows a large number—over fifty—of well-defined lines in the ultra-violet. I will show you these lines in another photograph taken with greater dispersion, and on which has also been photographed the spark spectrum of nickel. You will see that all these lines correspond absolutely to lines appertaining to the spark spectrum; in fact, the greater part of the lines in the spark spectrum are also shown in this flame spectrum. We have here another and very striking example of the fact discovered on the same day by Profs. Dewar and Liveing, and by Dr. Huggins, that the spectrum of luminous flames is not always continuous throughout its whole range, a fact which was at one time much debated and discussed.

One of the most remarkable discoveries made within the precincts of this Institution by that illustrious man whose centenary we celebrated last year was that of the connection between magnetism and light, which manifests itself when a beam of polarized light is sent through a substance while it is subjected to a strong magnetic field, under whose influence the beam of light is rotated through a certain angle. Dr. W. H. Perkin has prosecuted this discovery of Faraday's by a long series of most elaborate researches, and has established the fact that this power of magnetic rotation of various bodies has a definite relation to their chemical constitution, and enables us to gain a better insight into the structure of chemical compounds. Dr. Perkin has been good enough to investigate the power of magnetic rotation of the nickel carbonyl, and has found it quite as unusual as its chemical properties, and to be, with the sole exception of phosphorus, greater than that of any other substance he has yet examined.

The power of different bodies of refracting and dispersing a ray of light has been shown by the beautiful and elaborate researches undertaken many years ago by Dr. Gladstone—who has given an account of them in this theatre in 1875, and who has since continued them with indefatigable zeal—to throw a considerable light upon the constitution of chemical compounds.

I have investigated the refractive and dispersive powers of nickel carbonyl in Rome, in conjunction with Prof. Nasini. We found that the atomic refraction of nickel in the substance is nearly two and a half times as large as it is in any other nickel compound—a difference very much greater than had ever before been observed in the atomic refraction of any element. To give you some idea how these figures are obtained, Mr. Lennox will now throw on to the screen a beam of light through two superposed prisms, one filled with nickel carbonyl and the other with alcohol. You will notice that the lines of the spectrum on the top are turned much further to the left, showing the nickel carbonyl to possess a much greater power of refraction than alcohol, and you will also notice that it is much wider than the bottom spectrum, which shows the greater dispersive power of the nickel carbonyl.

It is now generally supposed that, if one element shows different atomic refractive powers in different compounds, it enters with a larger number of valencies into the compound which shows a higher refractive power. In accordance with this view, the very much greater refractive power of the nickel in the carbonyl would find an explanation in assuming that this element, which in all its other known combinations is distinctly bivalent, exercises in the carbonyl the limit of its valency, viz. 8, assigned to it by Mendeleeff, who placed it in the eighth group in his Table of Elements. This would mean that the one atom of nickel contained in the nickel carbonyl is combined directly with each of the four bivalent atoms of carbonyl, each of which would saturate two of the eight valencies of nickel, as is shown by this formula—



$$\begin{array}{ccccc} & & \mathrm{O} & & \\ & & \cdot\cdot & & \\ & & \mathrm{C} & & \\ & & \| & & \\ \mathrm{O:C} & = & \mathbf{Ni} & = & \mathrm{C:O} \\ & & \| & & \\ & & \mathrm{C} & & \\ & & \cdot\cdot & & \\ & & \mathrm{O} & & \end{array}$$

This view seems plausible, and in accordance with the chemical properties of the substance, and I should have no hesitation in accepting it if we had not, in the further pursuit of our work on metallic carbonyls, met with another substance—a liquid compound of iron with carbonic oxide—which in its properties bears so much resemblance to the nickel compound that one cannot assign to it a different constitution, whilst its composition makes the adoption of a similar structural formula next to impossible. It contains, for one equivalent of iron, five equivalents of carbonyl. To assign to it a similar constitution, one would, therefore, have to assume that iron did exercise ten valencies, or two more than any other known element, a view which very few chemists would be prepared to countenance. The atomic refraction of iron in this compound, which Dr. Gladstone has had the kindness to determine, is as unusual as that of the nickel in the nickel compound, and bears about the same ratio to the atomic refraction of iron in other compounds. We have, therefore, to find another explanation for the extraordinarily high atomic refraction of these metals in their compounds with carbon monoxide, which may possibly modify our present view on this subject. As to the structure of these compounds themselves, we are almost bound to assume that they contain the carbonyl atoms in the form of a chain.

The ferro-carbonyl is prepared in a similar manner to the nickel compound. The iron used is obtained by heating iron oxalate at the very lowest temperature possible. This carbonyl forms, however, with such very great difficulty, that we overlooked its existence for a long time, and great precautions have to be taken to obtain even a small quantity of it. It forms an amber-coloured liquid, of which I have a small quantity before me. It solidifies below $-21°$ C. to a mass of needle-shaped crystals. On heating the vapour to 180° C., it is completely decomposed into iron and carbonic oxide. The iron mirrors before me have been obtained in this way. Its chemical composition is $Fe(CO)_5$.

It is interesting that, within a short time after we had made known the existence of this body, Sir Henry Roscoe found it in carbonic oxide gas which had stood compressed in an iron cylinder for a considerable time, and expressed the opinion that the red deposit which sometimes forms in ordinary steatite gas-burners is due to the presence of this substance in ordinary illuminating gas. Its presence in compressed gas used for lime-lights has been noticed by Dr. Thorne, whose attention was called to the fact that this gas sometimes will not give a proper light because the incandescent lime becomes covered with oxide of iron.

M. Garnier, in a paper communicated to the French Academy of Sciences, supposes even that this gas is sometimes formed in large quantities in blast-furnaces when they are working too cold, and refers to some instances in which he found large deposits of oxide of iron in the tubes leading away the gas from these furnaces. I find it difficult to believe that the temperature of a blast-furnace could ever be sufficiently reduced as to give rise to the formation of this compound. On the other hand, it is highly probable that the formation of this compound of iron and carbonic oxide may play an important *rôle* in that mysterious process by which we are still making, and have been making for ages, the finest qualities of steel, called the cementation process.

The chemical behaviour of the substance towards acids and oxidizing agents is exactly the same as that of the nickel compound, but to alkalies it behaves differently. The liquid dissolves without evolution of gas. After a while a greenish precipitate is formed, which contains chiefly hydrated-ferrous oxide, and the solution becomes brown. On exposure to the air, it takes up oxygen; the colour changes to a dark red, whilst hydrated ferric oxide separates out.

We have so far not been able to obtain from this solution any compound fit for analysis, and are still engaged upon unravelling the nature of the reaction that takes place, and of the compounds that are formed.

Although the solution resembles in appearance to some extent the solutions obtained by treating potassium carbonyl with water, it does not give any of the characteristic reactions of the latter.

When speaking of potassium carbonyl, I mentioned that, by its treatment with water, croconate of potassium was obtained, which has the formula $K_2C_5O_5$. We have transformed this by double decomposition into ferrous croconate (FeC_5O_5), a salt forming dark crystals of metallic lustre resembling iodine, which is not volatile, and dissolves readily in water, the solution giving all the well-known reactions of iron and of croconic acid. You will note how entirely different the properties of this substance are from those of iron carbonyl, which I have described to you; yet, on reference to its composition, you will find that it contains exactly the same number of atoms of iron, carbon, and oxygen as the latter. This is a very interesting case of isomerism, considering that both compounds contain only iron, carbon, and oxygen.

The difference in the properties of these two bodies becomes explainable by comparing the structural formula of the two substances.

I would now call your attention to the great difference in the constitution of the potassium carbonyl and that of the nickel and ferro carbonyl. In the former the metal potassium is combined with the oxygen in the carbonyl; in the latter the metals nickel and iron are combined with the carbon of carbonyl. In the first case we have a benzole ring with its three single and three double bonds; in the second a closed chain with only single bonds. It is evident that the chemical properties of these substances must be widely different.

The ferro-penta-carbonyl remains perfectly unchanged in the dark, but if it is exposed to sunlight it is transformed into a solid body of remarkably fine appearance, of gold colour and lustre, as shown by the sample in this tube.

This solid body is not volatile, but on heating it in the absence of air, iron separates out and liquid ferro-carbonyl distils over. If, however, it is heated carefully in a current of carbonic oxide it is reconverted into the ferro-penta-carbonyl, and completely volatilized. We have so far found no solvent for this substance, so that we have no means as yet of obtaining it in a perfectly pure state. Several determinations of the iron in different samples of the substance have led to fairly concordant figures, which agree with the formula $Fe_2(CO)_7$, or di ferro-hepta-carbonyl.

The interesting properties of the substances described have naturally led us "to try," as Lord Kelvin once put it to me so prettily, "to give wings to other heavy metals." We have tried all the well-known and a very large number of the rarer metals; but with the exception of nickel and iron we have so far been entirely unsuccessful. Even cobalt, which is so very like nickel, has not yielded the smallest trace of a carbonyl. This led me to study the question whether, by means of the action of carbonic oxide, the separation on a large scale of nickel from cobalt could not be effected, which has so far been a most complicated metallurgical operation; and subsequently I was led to investigate whether it would not be possible to use carbonic oxide to extract nickel industrially direct from its ores.

It had been established that pure nickel prepared with very great precautions in a glass tube, could be partly volatilized by carbonic oxide, and that from the gas thus obtained the nickel could be separated again by heating. The questions to be studied were, therefore, whether it would be possible to reduce the ores, on an industrial scale, under such conditions as to obtain the nickel in a sufficiently finely divided and active a state that the carbonic oxide would volatilize it; whether such action would be sufficiently rapid to allow of its industrial application; whether it would be sufficiently complete to remove all the nickel from the ore; and whether none of the other constituents of the ore would pass with the nickel and render it unfit for use; and further, whether the nickel could be completely separated out of the gas within practical limits; and whether the recovered carbonic oxide could be made use of over and over again.

For solving these problems within the limits of the resources of a laboratory, I have devised apparatus which consists of a cylinder divided into many compartments, through which the properly prepared ore is passed very slowly by means of stirrers attached to a shaft. On leaving the bottom of this cylinder, the ore passes through a transporting screw, and from this to an elevator, which returns it to the top of the cylinder, so that it passes many times through the cylinder, until all the nickel is volatilized. Into the bottom of this cylinder we pass carbonic oxide, which leaves it at the top charged with nickel carbonyl vapour, and passes through the conduits shown here into tubes set in a furnace and heated to 200°. Here the nickel separates out from the nickel carbonyl. The carbonic oxide is regenerated and taken back to the cylinder by means of a fan, so that the same gas is made to carry fresh quantities of nickel out of the ore in the cylinder, and to deposit it in these tubes an infinite number of times.

Upon these principles Dr. Langer has constructed a complete plant on a Liliputian scale, which has been at work in my laboratory for a considerable time, and a photograph of which we will now throw on to the screen. You see here the volatilizing cylinder divided into numerous compartments, through which the ore is passing, and subjected to the action of carbonic oxide. At the bottom the ore is delivered into the transporting screw, passing through a furnace, and from this screw into an elevator, which returns the ore to the top of the cylinder, so that the ore constantly passes at a slow rate through the cylinder again and again, until the nickel it contains has been taken out. The carbonic oxide gas, prepared in any convenient manner, enters the bottom of the cylinder and comes out again at the top. It then passes through a filter to retain any dust it may carry away, and thence into a series of iron tubes built into a furnace, where they are heated to about 200° C. In these tubes the nickel carbonyl carried off by the carbonic oxide is completely decomposed, and the nickel deposited against the sides of the tubes is from time to time withdrawn, and is thus obtained in the pieces of tubing and the plates which you see on the table.

The carbonic oxide regenerated in these tubes is passed through another filter, thence through a lime purifier, to absorb any carbonic acid which may have been formed through the action of the finely-divided nickel upon the carbonic oxide, and is then returned through a small fan into the bottom of the cylinder. The whole of this plant is automatically kept in motion by means of an electric motor, and the gearing which you see here.

By means of this apparatus we have succeeded in extracting the nickel from a great variety of ores, in a time varying, according to the nature of the ore, between a few hours and several days.

Before the end of this year this process is going to be established in Birmingham on a scale that will enable me to place its industrial capacity beyond a doubt, so that I feel justified in the expectation that in a few months nickel carbonyl, a substance quite unknown two years ago, and to-day still a great rarity, which has not yet passed out of the chemical laboratory, will be produced in very large quantities, and will play an important *rôle* in metallurgy.

The process possesses, besides its great simplicity, the additional advantage that it is possible to immediately obtain the nickel in any definite form. If we deposit it in tubes we obtain nickel tubes; if we deposit it in a globe we obtain a globe of nickel; if we deposit it in any heated mould we obtain copies of these moulds in pure, firmly coherent, metallic nickel. A deposit of nickel reproduces the most minute details of the surface of the moulds to fully the same extent as galvanic reproductions. All the very numerous objects now produced by galvanic deposition, of which Mr. Swan exhibited here such a large and beautiful variety a fortnight ago, can thus be produced by this process with the same perfection in pure metallic nickel. It is equally easy to nickel-plate any surface which will withstand the temperature of 180° C. by heating it to that temperature and exposing it to the vapour, or even to a solution of nickel carbonyl, a process which may in many cases have advantages over electroplating. I have on the table before me specimens of nickel ores we have thus treated, of nickel tubes and plates we have obtained from these ores, and a few specimens of articles of pure nickel and articles plated with nickel which have been prepared in my laboratory. These will give you some idea of the prospects which the process I have described opens out to the metallurgist, upon whom, from day to day, greater demands are made to supply pure nickel in quantities. The most valuable properties of the alloy of nickel and iron called nickel-steel, which promises to supply us with impenetrable ironclads, have made an abundant and cheap supply of this metal a question of national importance. The inspection of the few specimens of articles of pure nickel and of nickel-plated articles will, I hope, suffice to show you the great facilities the process offers for producing very fine copies, and for making articles of such forms as cannot be produced by hydraulic pressure, the only method hitherto available for manufacturing articles of pure nickel.

The first practical use of the process has been made by Prof. Ramsay, who, for the purposes of a chemical investigation, made this beautiful little apparatus of pure nickel all in one piece, which he has kindly lent for exhibition to-night.

I began my lecture by bringing under your notice an idea of Liebig's which he published fifty-eight years ago. I have shown you how he himself elaborated this idea, and how it developed, until within recent years it has led to results of the highest scientific importance and probably of great practical utility.

Had Liebig all these results before his "mind's eye" when he penned those prophetic words I have quoted? This is a question impossible to answer. Who will attempt to measure the range of vision of our great men, who from their lofty pinnacle see with eagle eye far into the Land of Science, and reveal to us wonderful sights which we can only realize after toiling slowly along the road they have indicated? Whether Liebig saw all these results or not, it is due to him and to men like him that science continues its marvellous advance, dispersing the darkness around us, and ever adding to the scope and exactness of our knowledge, that mighty power for promoting the progress and enhancing the happiness of humanity.

NORTH-WESTERN DISTRICT OF BRITISH GUIANA.

At the meeting of the Royal Geographical Society on Monday evening, Mr. Everard im Thurn described the general characteristics of the new district in the north-west of British Guiana in the settlement and administration of which he has been employed for the last ten years. The colony of British Guiana he described as formed of a low swampy coast strip, often below the level of the sea, densely covered with mangroves, and intersected by rivers bound together by interlacing channels. Farther inland the mangroves pass into forests of tropical trees, which, as the land rises more steeply, are reduced to strips along the rivers, and finally merge into dry grassy uplands known as savannahs. The north-western district of the colony is officially defined as the territory bounded on the north by the Atlantic Ocean and the mouth of the River Orinoco; on the south by the ridge of land between the sources of the Amakuru, Barima, and Waini Rivers, and their tributaries, and the sources of the tributaries of the Cuyuni River; on the east by a line extending from the Atlantic Ocean in a southerly direction to the said ridge of land; on the south and on the west, by the Amakuru River and the line known as Schomburgh's line.

Mr. im Thurn's first task was to explore his territory, and this he did mainly by boat along the rivers and their connecting channels, traversing country never before visited by white men. The nature of this mode of travelling was very vividly described. On ascending the Moruka, the country on each side of the river was seen to become gradually more and more open—the river at last often winding through open savannahs, and broadening out here and there into pools so thickly set with water-lilies that the boat was forced through with difficulty. The waterway after some time leaves the river and passes along a narrow itabbo, or artificial water-path, which connects the Moruka with the Waini River. This connecting passage is about thirty miles long, and about ten miles is semi-artificial itabbo, made by the constant passage of the canoes of the Redmen through the swampy savannah, and very difficult to get through. Generally, it was hardly wider than the boat, and had many abrupt windings; the trees hung down so low over the water, that it was hard work either to force the boat under the low-lying branches, or to cut these away, and so make a passage. On either side of the channel the ground is so swampy as rarely to allow foothold of even a few inches in extent. The light hardly penetrates through the dense roof of leaves; and in the gloom under the roof only a few aroids, ferns, lilies, and orchids, and great masses of a palm previously undescribed.

The itabbo passed, the boat turned suddenly into the Barabara River itself, at first narrow, but soon widening and winding on its course through dense and unbroken bush, chiefly composed of the graceful, swaying manicole palms (*Euterpe edulis*). Very abundant, perched high up and low down among this dense bush, were great quantities of an orchid with stems eight and nine feet long, loaded with its countless butterfly-like yellow flowers (*Oncidium altissinum*). After a few miles the Barabara River led into the Biara, a river of much the same character, which, though naturally larger than the Barabara, was still so small as hardly to deserve more than the local name of creek. And, again, in a few miles the Biara carried the boat into the Baramanni River, which is about 100 or 150 yards wide, and very deep. This is, in fact, not a river at all, but a very elongated lake or lagoon, of perhaps twenty miles in length, the lower end opening into the Waini, while the upper end discharges part of its surplus water into the sea. Anything more maze-like than the itabbo between the Waini and Barima Rivers it is impossible to imagine.

On the Aruka, a large tributary of the Barima, the curious Arawack game of the Macquari whip is played, the essential feature of which is a testing of endurance by means of alternately giving and receiving severe cuts with a somewhat severe whip. This extraordinary performance, accompanied with much drinking and with invariable good humour, is carried on for some days in accordance with a fixed ritual, the blows, which are received by the players on the calves of their legs, being so severe as to draw much blood. The river, too, must at one time have been the site of a Redskin civilization far superior to, and very different from, any known previously of the early inhabitants of Guiana; for there are on it considerable deposits of pottery ornamented with incised patterns, and even very abundantly with grotesque figures of men and animals in very high relief. To estimate the significance of this latter fact, it must be remembered that none of the known early inhabitants of Guiana have advanced in the important primitive art of pottery beyond the stage of making vessels of two or three definite and very simple shapes, which are almost invariably entirely without ornament, or are at best, in a very few cases, ornamented with a simple pattern painted on the flat surface.

The Warrau Redmen inhabiting a neighbouring region have recourse to a picturesque game in order to decide disputes amicably. For this purpose, on an appointed day both parties come together on some open space, such as this sand-bank, each man or boy provided with a large shield made of the leaf-stalks of the aeta palm (*Mauritia flexuosa*). After much shouting and dancing in two opposed lines, the shields of the one party are pushed against those of the other, and by this means the members of each party endeavoured by sheer strength to overthrow, or at least to force back from their position, the members of the other party; and the right in the matter in dispute is considered to lie with whichever party proves itself the stronger in this contest. The game is peculiar to the swamp Warraus, who live in the swamps of the mouths of the Orinoco, and live here chiefly on the aeta palm, not cultivating any food-stuff, but eating the fruit of this palm and the pith of its stem, not making any fermented drink, as other Redmen do, but drinking only water and the sap of this same palm, building their houses, not as Humboldt thought, actually *in* these palms, but yet entirely, floor, posts, and roof, *of* the various parts of this palm. The physical features of the north-western district are like, yet in some respects different from, those of the rest of the colony. The watershed from which the main rivers, the Waini, Barama, Barima, and the Amakuru, run down to the sea, is here nearer to the coast-line than it is further south. Two more important consequences arise from this. The bare dry savannah of the interior of other parts of the colony is here unrepresented, the whole district being practically within the forest belt. And the rivers are both shorter and deeper, though their mouths are very wide. Moreover, these rivers are curiously connected both by a remarkably elaborate network, probably hardly paralleled in any other part of the world, of natural and semi-natural water channels—such as those described—and by an almost equally elaborate network of Redmen's paths through the forest.

The inhabitants of this district were, ten years ago, Redmen, and Redmen only. Their distribution is interesting when taken in connection with the distribution of their kind throughout the colony. The Redmen of Guiana consist of many small tribes, the best known of which are the Arawacks and the so-called Caribs—true Caribs they are preferably called. These two last-named tribes owe the fact that they are the best known to the circumstance that they shared between them the West Indian Islands south of Jamaica at the time of their discovery by Columbus; and they are the last remnants of those people who were the victims of that brutal policy of extermination by cruelty followed by the Spanish conquerors of the New World. The north-western district is some 9500 square miles in extent, and rises gradually from the sea to the range of somewhat higher land, which is represented, with some exaggeration, on most existing maps as the Sierra Imataca range of mountains, but which, within the limits of British Guiana, never attains a general level of more than 300 or 400 feet. The lower or alluvial part of this country consists of some of the richest soil in the world. Parts which have since been taken in and drained now yield crops of tropical produce of simply amazing abundance. As an illustration, a garden which hardly two and a half years ago was cleared and drained already has in it avenues of trees (*Casuarina*) of over 40 feet high, which were then planted. On the other hand, the higher part of the new district is being fast overrun by very successful gold-diggers.

For geographical reasons the most convenient centre from which to administer the district was at the point at which the Morawhanna leaves the Barima. This is near the centre of the waterway which traverses the northern part of the colony from the sugar fields about the mouth of the Essequibo to its northern limits on the Orinoco, by which, in the absence of roads, all traffic from the Orinoco to the older established parts of the colony must necessarily pass. Here, therefore, the central station, with the Government Agency, the police barracks, the hospital, and the other buildings, public and private, which go to make up the chief township, have been placed, and are fast being added to. A large station, with the other necessary accommodation, was also placed at the northern end of the waterway, on the mouth of the Amakuru; and other stations have been placed at intervals along the whole line.

SCIENTIFIC SERIALS.

THE *American Meteorological Journal* for May contains a paper read by Prof. W. M. Davis, before the New England Meteorological Society, entitled "Meteorology in the Schools." It points out the best plan to be adopted by a teacher to give his pupils a sound knowledge of the subject, and it will be found full of interest for many who may have made considerable progress in the study of meteorology. The complete solution of weather changes is far beyond the meteorology of the day, but the paper will teach the student to recognize the great difficulties attendant upon successful weather-predictions, and to discriminate between these and the predictions of those who pretend to outline the course of meteorological events for months ahead.—Thunderstorms in New England during the year 1886, by R. De C. Ward. The observation of thunderstorms was taken as a special subject of investigation by the New England Meteorological Society in the years 1885–87, and this paper is a preliminary report on the investigation, to be eventually published by the Harvard College. The storms were most frequent between May and August, and between 5h. and 7h. p.m. The average rate of movement throughout the year was 35 miles an hour. The influence of the tides on the direction of the storms is said to be brought out in several reports.—The storm of March 1–4, 1892, by J. Warren Smith. This storm was so severe in the New England States, and the snowfall and drift so heavy, as to cause in many places the cessation of all outside business; trains were blocked, and much damage done to shipping from the violence of the wind.

THE *American Meteorological Journal* for June contains the following original articles:—Flood-stage river predictions, by Prof. T. Russell. The paper gives some account of the methods by which the rules for river-stage predictions are derived. A river-stage is the vertical height of the water surface above the plane of low water, observed with a gauge. There are about 150 gauge stations maintained at various points in the United States. The predictions are mainly based upon observation of the stages and rises at certain points of a stream, and upon a consideration of what has occurred in previous cases, from which data factors are calculated. As a rule, rainfall observations are of little use in such predictions.—The first scientific balloon voyage, translated by R. De C. Ward, from an article by Dr. Hellmann. (See NATURE, vol. xlv. p. 471.)—Snowstorms at Chicago, by A. B. Crane. The writer has tabulated the records relating to the subject from 1879-90, and has discussed them with reference to the meteorological conditions prior to the storm. The heaviest storms occurred in January, the average temperature being 21°·4. He found that before the storms the temperature nearly always rises, and that it rarely falls for twenty-four hours previously.—The eye of the storm, by S. M. Ballou. This name is given to the calm area in the centre of a cyclone, where clear sky is generally visible. The author quotes accounts by various observers, and a review of the different explanations of the phenomenon.—Shall we erect lightning-rods?, by A. McAdie. The question being whether it is cheaper to insure buildings than to incur the expense of erecting lightning-rods, the author quotes a number of authorities in support of the advisability of putting up rods, and gives rules to be observed in doing so.

Bulletin of the New York Mathematical Society, vol. i., Nos. 8 and 9 (New York, 1892).—The illustrious German mathematician, Leopold Kronecker, died recently at Berlin (December 29, 1891). No. 8 (pp. 173–84) opens with a most interesting article, by H. B. Fine, entitled "Kronecker and his Arithmetical Theory of the Algebraic Equation." This is biographical and analytical. A short note, by Prof. Cajori, follows, on the "Multiplication of Series." The concluding note is by Dr. Macfarlane, "On Exact Analysis as the Basis of Language." This is a brief abstract of a paper read before the Society (March 5, 1892).—No. 9 gives an account of a recent paper in the *Mathematische Annalen* (vol. xxxviii.), by M. Hilbert, under the head "Topology of Algebraic Curves." The writer, L. S. Hulburt, recasts the theory, with the view of making the theory more intelligible, and corrects some slight inaccuracies. Dr. Merriman abstracts a paper (read before the Society) on "Final Formulas for the Algebraic Solution of Quartic Equations." This number closes with a full account of Poincaré's "Mécanique Céleste," by E. W. Brown. The usual short notes and list of new publications are given at the end of each number.

Memoirs of the Mathematical Section of the Odessa University, vol. xiii.—On the theory of linear differential equations, by M. Rudzky.—The mechanics of a system subject to similar changes, by D. Seiliger, part iii. The paper is followed by a description of an apparatus, the "homoyograph," three spots of which always take such positions as to make similar triangles.—Experimental researches into the compressibility of glass and mercury, by G. De-Metz. The absolute compressibility of mercury has been determined on the two methods of Regnault and Jamin, as also on a third method which results from the equations of Lamé in his "Leçons sur l'Élasticité," and the seventh memoir of Regnault. The results arrived at in these very elaborate researches are very near to those arrived at by Amagat.—Volume xii. of the same periodical consists of a work by J. Timtchenko, on the foundations of the theory of analytical functions. The aim of the author is to contribute towards the elaboration of a *general* theory of functions which would include Weierstrass's theory as well. The first part, now published, contains the historical review of the development of the theory.

Bulletin de la Société des Naturalistes de Moscou, 1891, Nos. 2 and 3.—The Speeton clays and their equivalents, by A. Pavloff and G. W. Lamplugh.—Contributions to the study of molecular forces in chemically simple bodies, on the ground of thermodynamics, by J. Weinberg.—Studies on the development of Amphipodes, part v., by Madame Catherine Wagner (in French, with two plates). The development of the embryo of the *Melita palmata* is apparently quite similar to that of *Gammarus* and *Caprella* in its earlier stages, but the microscopic observation of cuttings through the embryo discloses several interesting peculiarities, which are described and illustrated.—What is the Hipparion?, by Marie Pavloff (in French), being an answer to critical remarks, by M. Trouessart, in *Annuaire Géologique Universel*, tome vi., relative to Marie Pavloff's work on the evolution of Ungulates.—On a new apparatus for determining the moment of inertia of a body, by N. Joukovsky (in French).—On *Pteromonas alata*, Cohn, by M. Golenkin (in German).—The present state of our knowledge of the contents of the cells of the Phycochromaceæ, by Valerian Deinega (in German). The author has come to no definite results as to the nucleus in the Phycochromaceæ, especially in the thread-like species; new colouring methods ought to be discovered.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 2.—"Supplementary Report on Explorations of Erect Trees containing Animal Remains in the Coal-formation of Nova Scotia." By Sir J. William Dawson, F.R.S.

To the memoir which I had the honour to present to the Royal Society on this subject in 1882[1] I appended a note from Dr. Scudder, of Cambridge, U.S., so well known for his researches in fossil Insects and Arachnidans, in which he gave a preliminary account of the remains of Arthropods in my collections which I had submitted to him. He has only in the present year completed his examination of these remains, most of which are very fragmentary, and much damaged by unequal pressure. The result has been embodied in a Report on Canadian Fossil Insects, now in course of publication by the Geological Survey of Canada.

In this Report he will describe from the contents of the Sigillarian stumps extracted by me, with the aid of the grant of this Society, three new species of Myriapoda, making, with the five previously known from these remarkable repositories, eight in all, belonging to two families, Archiulidæ and Euphoberidæ, and to three genera, *Archiulus*, *Xylobius*, and *Amynilyspes*. The three new species are *Archiulus euphoberioides*, Sc., *A. Lyelli*, Sc., and *Amynilyspes* (sp.). The remains of Scorpions he refers to three species, *Mazonia acadica*, Sc., *Mazonia* (sp.), and a third represented only by small fragments. The characters of the species referred to *Mazonia* he considers as tending to establish the generic distinctness of *Mazonia* from *Eoscorpius*. Dr. Scudder also notices the fragment of an insect's head containing part of a facetted eye, mentioned in my memoir, and considers it probably a portion of a Cockroach.

Much credit is due to Dr. Scudder for the care and skill with which he has worked up the mostly small and obscure fragments which I was able to submit to him, and which are probably little more than *débris* of the food of the Amphibians living for a time in these hollow stumps, and devouring such smaller animals as were so unfortunate as to be imprisoned with them. In this connection the suggestion of Dr. Scudder is worthy of attention, that the scaly armour of the smaller Microsaurians may have been intended to defend them against the active and venomous Scorpions which were their contemporaries, and some of which were sufficiently large to be formidable antagonists to the smaller land Vertebrates of the period.

The report of Dr. Scudder will complete the account of the land animals of the erect Sigillariæ of the South Joggins, unless by new falls of the cliff fresh trees should be exposed. From 1851, when the first remains were obtained from these singular repositories by the late Sir Charles Lyell and the writer, up to the present time, they have afforded the remains of twelve species of Amphibians, three land Snails, eight Millipedes, three Scorpions, and an Insect.

The type specimens of these animals have been placed in the Peter Redpath Museum of McGill University, and such duplicates as are available will be sent to the British Museum and that of the Geological Survey of Canada.

June 16.—"On the Estimation of Uric Acid in Urine." By F. Gowland Hopkins.

The process described depends upon the complete insolubility of ammonium urate in saturated solutions of ammonium chloride.

The pure chloride is powdered, and added to the sample to complete saturation. After two hours' standing, the whole of the uric acid separates as biurate of ammonium. The urate is then decomposed with hydrochloric acid, and the liberated uric acid determined by any approved method. In contrast to the well-known Fokker-Salkowski process the separation is rapid and complete.

The author has experimented with permanganate solutions for the titration of the separated uric acid, and finds that accurate results may be obtained by their employment. For this purpose the uric acid is dissolved in 100 cc. of water, with a minimum of Na_2CO_3, 20 cc. of strong H_2SO_4 being then added, and the solution immediately titrated with one-twentieth normal permanganate of potassium. The addition of 20 per cent. H_2SO_4 to the previously cooled solution of sodium urate yields just such a temperature (about 60°C.) as is requisite for a determinate reaction. 1 cc. of the permanganate solution is equal to 0·00375 grm. uric acid.

Physical Society, June 24.—Prof. A. W. Rücker, F.R.S., in the chair.—The following communications were made:—On breath figures, by Mr. W. B. Croft. After mentioning the observations of early experimenters on the subject, the author described a method which he found to give the best results. A coin is placed on a glass plate for insulation; another glass plate, which is to receive the impression, is well polished and laid on the coin, whilst a second coin is placed above the first. The coins are put in connection with the poles of an electrical machine, giving one-inch sparks for two minutes. When the coins are removed and the glass breathed on, clear frosted pictures of the coins are seen on the glass. The microscope shows that moisture is deposited on the whole surface, the size of the minute water granulation increasing as the part of the picture is darker in shade. The thickness of the glass seemed to make no difference to the result, and several plates and coins might be piled up alternately. If carefully protected, time appears to have little effect on the figures, but they can be removed by rubbing whilst the glass is moist. Failures and their causes were discussed, and the more complex phenomena produced by strong discharges described. It was also pointed out that breath figures could be produced by laying a coin on a freshly split surface of mica, and that a coin laid on glass for some time leaves its traces. Perfect reproductions of printed matter have been obtained by placing a paper printed on one side only between two sheets of glass for ten hours. Some substances, such as silk in contact with glass, give white figures; whilst wool, cotton, &c., give black ones. Various analogous effects are noticed in the paper, and the several views put forward in explanation of the phenomena examined.—A communication on the same subject, from the Rev. F. J. Smith, was read by Prof. Perry. He had investigated some of the effects, and succeeded in photographing the impressions, prints from which were shown. He had also examined the influence of various gases on the results, and found that oxygen gave the best figures. In a vacuum no figures could be obtained. The effect of temperature had also been tested. Prof. S. P. Thompson said details of early researches were given in *Poggendorff's Annalen* for 1842. It was there pointed out that better results were obtained by putting a spark gap between the coin and the machine. Since the effects did not depend on the way in which the sparks passed, he thought it was probable that electrical oscillations were involved. He himself had worked at the subject in 1881, and recently repeated some of the experiments. Figures could be produced on almost any polished surface; he got the best results by using a small induction coil giving 3 mm. spark, for about five seconds. In 1881 he accidentally noticed that photographs could be got on ebonite. Hot coins put on uncleaned glass gave good breath figures. A member said that instead of breathing on the plates, he and Mr. Garrett had sifted finely powdered red lead on them, to get the figures. They had also fixed the figures by etching with hydrofluoric acid. Mr. Croft exhibited some figures he obtained two years ago, which were still quite distinct.—On the measurement of the internal resistance of cells, by Mr. E. Wythe Smith. After referring to the methods hitherto used, the author described a modification of Mance's test which he had recently devised. One pole of the battery to be tested is connected to the similar poles of two other batteries; each battery has a separate circuit, through which currents are allowed to pass. Selecting a point A at the opposite pole of the battery to be tested, points B and C in the circuits of the auxiliary batteries are found, whose potentials are equal to that of A. The resistances between each pair of points AB, AC, BC, are then measured by a Wheatstone's bridge. Calling these resistances R_1, R_2, and R_3 respectively, it is shown that the internal resistance required is given by the formula $b = x + \frac{x^2}{r} + \frac{x^3}{r^2} + \&c.$, where $x = \frac{R_1 + R_2 - R_3}{2}$, and r is the external resistance of the circuit containing the battery tested. For an accumulator discharging, $b = x$ to within about 2 per cent. Prof. Perry inquired how far the results obtained agreed with those got by the older methods, and whether they depended on the time the keys were kept down. In the old methods it was assumed that an instantaneous rise in P.D. occurred on breaking the circuit. This might or might not be true. He was inclined to regard the P.D. and current as functions, both of resistance and time. The behaviour of cells seemed to indicate the existence of something like capacity, or rather, capacities and resistances in series. Prof. Ayrton said the paper was of great interest, for it made possible what could not be done before, viz. to find the resistance of a cell without appreciably altering the current through it. Although the new method required more cells, this was not prohibitive, for the result sought was of considerable scientific importance. The same method was applicable for finding the resistance of dynamo-armatures when working, a quantity which had hitherto been unattainable by direct measurement. Mr. Lane Fox said the perplexing changes in the P.D. of secondary cells were to be accounted for by changes in the electrolyte, which occurred in the pores of the plates. He could detect no flaw in the reasoning given in the paper. Dr. Sumpner remarked that the method was a valuable one, for it depended on bridge tests which could be made with considerable accuracy. On the other hand, it was a false zero method, and therefore liable to errors arising from changes of this zero. Prof. Ayrton pointed out that these errors could be eliminated by reversing the bridge battery. Mr. Rimington said although the testing currents were small they might affect the E.M.F., and thus introduce an error in b. This might be tested by using alternate currents and a telephone. In reply to Prof. Perry, Mr. Smith said the results agreed with those obtained by the older methods to within the limits of accuracy obtainable by the latter methods; this might amount to something like 15 per cent.—On the relation of the dimensions of physical quantities to directions in space, by Mr. W. Williams. In February 1889, Prof. Rücker recalled attention to the fact that, in the ordinary dimensional formulæ for electrical quantities, the dimensions of μ (permeability) and k (specific inductive capacity) are suppressed. In the discussion on that paper Prof. S. P. Thompson pointed out that lengths should be considered as having direction as well as magnitude, for, if so regarded, difficulties arising from different units, such as *couple* and *work*, having the same dimensions, would be avoided. Developing this idea, the author takes three mutually perpendicular lines, along which lengths are measured. Calling unit lengths along these lines X, Y, and Z respectively, the various dynamical units, such as velocity, acceleration, force, work, &c., are expressed in terms of M, T, X, Y, and Z. The formulæ then denote the directional as well as the numerical relations between the units, and the dimensional formulæ are therefore regarded as the symbolical expressions of the physical nature of the quantities, so far as they depend on lengths, mass, and time. In this system areas and volumes are represented by products of different vector lengths instead of by powers of a single length, and angles and angular displacements by quotients of rectangular vectors, instead of being pure numbers. For physical purposes pure numbers may be defined as ratios of concretes of the same kind similarly directed (if directed at all). A plane angle has dimensions $X^{-1}Y$, X being in the direction of the radius, and Y that of the arc, whilst solid angles have dimensions YZX^{-2}, and radii of curvature Y^2X^{-1}. It is also shown that π is a concrete quantity of the dimensions either of plane or of solid angle. This is of considerable importance in connection with the radial and circuital fluxes in the electromagnetic field. In deducing the dimensional formulæ for electrical and magnetic units, the rational and simplified relations given by Mr. Oliver Heaviside in the *Electrician* of October 16 and 30, 1891, are used. Instantaneous axes are taken at any point of an isotropic medium (the ether) such that X coincides with the electrical displacements, Y with that of the magnetic displacement, and Z with the intersection of the two equipotential surfaces at that point. Starting with the relation μH = energy per unit volume, the formulæ for the various quantities in terms of μ are obtained. These simplify down to those of the ordinary electro-magnetic system by putting $\mu = 1$ and suppressing the distinction between X, Y, and Z. Similarly, commencing with kE^2 = energy per unit volume, formulæ in terms of k are obtained, which, when simplified as above, give those of the ordinary electrostatic system. Examples of the consistent way in which the results work out are given in the paper, and the whole subject is discussed in detail, both by Cartesian and vectorial methods. The formulæ in terms of μ and k are used to trace out and examine the various analogies between electro-magnetism and dynamics, thereby obtaining a connected dynamical theory of electromagnetism. Inquiry is then made as to what dimensions of μ and k in terms of M, T, X, Y, Z, render the interpretation of electrical and magnetic units simple, natural, and intelligible as a whole. The conditions imposed (for reasons stated in the paper) are, first, that the dimensions of μ and k satisfy the relation $[\mu k] = Z^2T^{-2}$; second, that the powers of the fundamental units in the dimensional formulæ shall not be higher or lower than those found in the formulæ of the ordinary dynamical quantities; and, third, that quantities which are scalar or directed must also be scalar or directed when their dimensions are expressed absolutely. Subject to these conditions, it is shown that the possible dimensional values of μ and k are eight in number. Of these only two lead to intelligible results. These are—

---

[1] Phil. Trans., 1882, p. 621.

$$(1)\ \mu = M(XYZ)^{-1} \text{ and } k = M^{-1}\,XYZ^{-1}T^2.$$

and

$$(2)\ \mu = M^{-1}XYZ^{-1}T^2 \text{ and } k = M(XYZ)^{-1}.$$

According to (1), μ is the density of the medium, electrical energy is potential, and magnetic energy kinetic. By (2), k is the density of the medium, electrical energy is kinetic, and magnetic energy potential. Full interpretations of the dimensional formulæ of all the electro-magnetic quantities, as obtained in accordance with the above conditions, are given in the paper. Prof. S. P. Thompson said the paper was a very important one, and thought the idea of finding dimensions for μ and k which would rationalize the ordinary dimensional formulæ a great step. The use of vectors was a valuable feature, whilst the employment of X, Y, and Z instead of L removed many difficulties connected with dimensional formulæ. Other difficulties might be cleared up by paying attention to the signs of the vector products and quotients, and to the order in which the symbols were written. Another important matter was the use of Mr. Heaviside's "rational units," a system which merited serious attention. In conclusion, Prof. Thompson expressed a hope that, in accordance with the resolution of the Electrical Congress at Frankfort, both permeability and specific inductive capacity should be designated by Greek symbols. Prof. O. Henrici expressed his admiration of the way in which the subject had been treated in the paper. He had long held that clear ideas of physical quantities were best got by vectorial methods. He also congratulated the author on his treatment of plane and solid angles as concrete quantities. In a communication addressed to the Secretaries, Prof. O. J. Lodge remarked that physicists in England were more or less familiar with the advantages of retaining μ and k in dimensional expressions before Prof. Rücker's paper of February 1889 brought the matter closely home to students. The system of mechanical dimensions suggested for electrical quantities in an Appendix to "Modern Views of Electricity" was not put forth as the only one possible, but as one having certain probabilities of truth in its favour. Prof. Rücker said that, although Mr. Williams and himself had talked over certain minor points in the paper, the main ideas brought forward were quite original, having been fully developed by Mr. Williams before he mentioned the subject to him (Prof. Rücker).—A paper on molecular forces, by Mr. W. Sutherland, communicated by Prof. Carey Foster, was taken as read. The Chairman announced that both this paper and that of Mr. Williams would be printed in the *Philosophical Magazine* during the long vacation, so that they could be fully discussed early next session.

Linnean Society, June 16.—Prof. Stewart, President, in the chair.—Mr. F. Enock exhibited some specimens of the Mustard Beetle, and gave an account of its recent depredations as observed by himself. So numerous was it that in walking down a single row of mustard, a distance of sixty-five yards, he had captured with a butterfly net upwards of 15,000, as he subsequently ascertained by counting a portion and weighing the remainder. The crop of mustard thus affected he regarded as destroyed.—Mr. R. I. Pocock exhibited and made some remarks upon a species of Peripatus (*P. juliformis*) from St. Vincent, of which five specimens had been collected by Mr. H. H. Smith for the Committee investigating the fauna and flora of the Lesser Antilles. The species was originally described so long ago as 1826, by the Rev. L. Guilding (*Zoological Journal*, vol. ii.), but from that time until the present no additional specimens had been procured there. As Guilding's types had been lost, and his descriptions are wanting in detail, this rediscovery was of considerable interest.—Mr. George Murray exhibited and described the type of a new order of Algæ, to which the name *Splachnidium rugosum* was given.—A paper was read by Prof. J. R. Henderson, entitled "Contributions to Indian Carcinology," and embodied an account of several little-known Crustaceans, and descriptions of some new species.—Mr. H. B. Guppy read a paper on "The Thames as an Agent in Plant Dispersal," in which several interesting facts were brought out, the observations being illustrated by specimens collected by the author, and a useful record given of the effects of exposure to sea-water, and of freezing, upon the germinating power of seeds.—Prof. F. Oliver gave an abstract of observations made by Miss M. F. Ewart, on some abnormal developments of the flowers of *Cypripedium*, illustrated by effective diagrams in coloured chalk.—Mr. R. I. Pocock contributed some "Supplementary Notes on the Fauna of the Mergui Archipelago," the result of his examination of some fresh material which had lately come to hand.—The evening was brought to a close by an exhibition by Mr. Carruthers, with the aid of the oxy-hydrogen lantern, of some beautiful slides of sections of fossil plants. A second series, zoological, exhibited by the President, included several minute organisms of extreme interest.—This meeting brought the session of 1891–92 to a close.

Anthropological Institute, June 21.—Edward B. Tylor, F.R.S., President, in the chair.—Dr. R. Wallaschek read a paper entitled "An Ethnological Inquiry into the Basis of our Musical System." In the course of the paper he pointed out that harmony is not a modern European invention, but known to many savage tribes, and even to the Hottentots and Bushmen. A regular bass accompaniment (to distinguish it from songs in harmonious intervals) is far more seldom to be met with, as the extreme simplicity of primitive songs does not admit of much variety in accompaniment. On the other hand, some savage tribes (Hottentots, Malays, Negroes) show an astonishingly great talent in accompanying European tunes by ear. Both keys, the major as well as the minor, occur in the songs of primitive races. Minor chords also occur occasionally. There is no internal connection between a peculiar key and a peculiar mood or disposition of mind. The diatonic scale does not seem to be a more recent invention than the pentatonic. The most ancient diatonic division is to be met with in instruments (pipes, flutes) of the Stone period. This early occurrence seems to be due to the fact that the diatonic scale is the most natural for the player's fingers, while it is at the same time the most effective. The diatonic system is neither an "artistic invention," nor a "scientific discovery," nor is it "natural" for the voice or the ear, nor based upon the laws and conditions of sounds, but it is the most natural for the hand, and the most practical for playing instruments.—Prof. Basil Hall Chamberlain then read a paper on some minor Japanese religious practices. After mentioning various miscellaneous usages and superstitions, the author treated chiefly of Japanese pilgrims and their ways, illustrating his remarks by an exhibition of a large collection of charms, sacred pictures, pilgrims' dresses, &c., brought together partly by himself, partly by Mr. Lafcadio Hearn. The collection included articles from the Shinto shrines of Ise and Izumo, from the "Thirty-three Holy Places" of Central Japan, from the "Eighty-eight Holy Places" of the island of Shikoku, from the temple of Asakusa in Tokyo, &c. The most curious was a sacred fire-drill from the great Shinto shrine of Izumo. This, together with a few of the other articles, has been presented by Prof. Chamberlain to the Pitt-Rivers Museum at Oxford. Another feature of the paper was the translation given of a Buddhist legend explaining the origin of the pilgrimage to the "Thirty-three Holy Places," and of some of the hymns intoned by the pilgrims.

Geological Society, June 22.—W. H. Hudleston, F.R.S., President, in the chair.—The following communications were read:—Contribution to a knowledge of the Saurischia of Europe and Africa, by Prof. H. G. Seeley, F.R.S. The Saurischia are defined as terrestial unguiculate Ornithomorpha, with pubic bones directed downward, inward, and forward to meet in a ventral union. The forms of the pelvic bones vary with the length of the limbs, the acetabulum becoming perforate, the ilium more extended, the pubis and ischium more slender, and the sacrum narrower as the limb-bones elongate. The order is regarded as including the Cetiosauria, Megalosauria, and Aristosuchia or Compsognatha. The Cetiosaurian pelvis has been figured in the *Quart. Journ. Geol. Soc.*; and a restoration is now given of the pelvis in *Megalosaurus*, *Streptospondylus*, and *Compsognathus*. The characters of the skull are evidenced by description of the hinder part of the skull in *Megalosaurus* found at Kirklington, and preserved in the Oxford University Museum. In form and proportions it closely resembles *Ceratosaurus*, and the corresponding region of the head in Jurassic Ornithosauria. The brain-cavity and cranial nerves are described, and contrasted with those of *Ceratosaurus*. The skull in Cetiosauria, known from the American type *Diplodocus*, is identified in the European genus *Belodon*, which is regarded as a primitive Cetiosaurian. Part 2 discusses the pelvis of *Belodon*, restored from specimens in the British Museum, and regarded as Cetiosaurian. A restoration of the shoulder-girdle is made, and found to resemble that in Ichthyosaurs, Anomodonts, and Dinosauria. The vertebræ in form and articulation of the ribs are Saurischian, the capitular and tubercular facets being vertical in the dorsal region, and not horizontal as in Crocodiles. The humerus shows some characters in common with that of *Stereorachis dominans*, in the epicondylar groove. In general character the limb-bones are more crocodilian than the axial skeleton. The interclavicle is described and regarded as a family characteristic of the Belodontidæ. In the third part an account is given of *Staganolepis*, which is regarded as showing a similar relation with the Megalosauria, to that of *Belodon* with the Cetiosauria. This interpretation is based chiefly upon the identification of the pubic bone in *Staganolepis*, which has the proximal end notched as in *Zanclodon* and *Streptospondylus*; and the inner ridge at the proximal end is developed into an internal plate. A note follows on the pelvis of *Aëtosaurus*, which is also referred to the Saurischia on evidence of its pelvic characters, approximating to the Cetiosaurian sub-order. Part 4 treats of *Zanclodon*, which is regarded as closely allied to *Massospondylus*, *Euskelesaurus*, and *Streptospondylus*. It is founded chiefly on specimens in the Royal Museum at Stuttgart, and in the University Museum at Tübingen. The latter are regarded as possibly referable to *Teratosaurus*, but are mentioned as *Zanclodon Quenstedti*. The pelvis is described and restored. *Zanclodon* has the cervical vertebræ relatively long, as compared with *Megalosaurus*, and small as compared with the dorsal vertebræ, which have the same Teleosauroid mode of union with the neural arch as is seen in *Streptospondylus* and *Massospondylus*. The sternum, of Pleininger, is the right and left pubic bones; but there is much the same difference in the proximal articular ends of those bones in the fossils at Stuttgart and Tübingen, as distinguishes corresponding parts of the pubes in *Megalosaurus* and *Streptospondylus*. The ilium is more like that of *Palæosaurus* and *Dimodosaurus*. The limb-bones and digits are most like those of *Dimodosaurus*, but the teeth resemble *Palæosaurus*, *Euskelesaurus*, *Megalosaurus*, and *Streptospondylus*. Part 5 discusses *Thecodontosaurus* and *Palæosaurus* upon evidence from the Dolomitic Conglomerate in the Bristol Museum. An attempt is made to separate the remains into those referable to *Thecodontosaurus* and those belonging to *Palæosaurus*. The latter is represented by dorsal and caudal vertebræ, a scapular arch, humerus, ulna (?), metacarpals, ilium, femur, tibia, fibula, metatarsals, and phalanges. These portions of the skeleton are described. There is throughout a strong resemblance to *Zanclodon* and other Triassic types. A new type of ilium, and the humerus originally figured, are referred to *Thecodontosaurus*. Part 6 gives an account of the South African genus *Massospondylus*. It is based partly upon the collection from Beaucherf, in the Museum of the Royal College of Surgeons, referred to *M. carinatus*; and partly upon a collection from the Telle River, obtained by Mr. Alfred Brown of Aliwal North, referred to *M. Browni*. The former is represented by cervical, dorsal, sacral, and caudal vertebræ; ilium, ischium, and pubis; femur, tibia; humerus, metatarsals, and phalanges. The latter is known from cervical, dorsal, and caudal vertebræ, femur, metatarsals, and bones of the digits. The affinities with *Zanclodon* are, in some parts of the skeleton, stronger than with *Euskelesaurus*. Part 7 gives an account of *Euskelesaurus Browni*, partly based upon materials obtained by Mr. Alfred Brown from Barnard's Spruit, Aliwal North, and partly on specimens collected by the author, with Dr. W. G. Atherstone, Mr. T. Bain, and Mr. Alfred Brown, at the Kraai River. The former series comprises the maxillary bone and teeth, vertebræ, pubis, femur, tibia and fibula, phalanges, chevron bone and rib. The latter includes a cervical vertebra and rib, and lower jaw. The teeth are stronger than those of *Teratosaurus*, or any known Megalosaurian. The anterior part of the head was compressed from side to side, and the head in size and form like *Megalosaurus*, so far as preserved. The pubis is twisted as in *Staganolepis* and *Massospondylus*, with a notch instead of a foramen at the proximal end, as in those genera; and it expands distally after the pattern of *Zanclodon*. The chevron bones are exceptionally long, and the tail appears to have been greatly elongated. The femur is intermediate between *Megalosaurus* and *Palæosaurus*, but most resembles *Zanclodon* and *Massospondylus*. The tibia in its proximal end resembles many Triassic genera; and in its distal end is well distinguished from *Massospondylus* by its mode of union with the astragalus. The claw-phalanges are convexly rounded, being wider than is usual in Megalosauroids. The lower jaw from the Kraai River gives the characters of the articular bone, and the articulation, as well as of the dentary region and teeth. The cervical vertebra is imperfect, but is remarkable for the shortness of the centrum, being shorter than in *Megalosaurus*. In Part 8 an account is given of *Hortalotarsus skirtopodus* from Barkly East, preserved in the Albany Museum. It is a Euskelesaurian, and exhibits the tibia and fibula, and tarsus. There is a separate ossification for the intermedium, which does not form an ascending process; and the astragalus is distinct from the calcaneum. The metatarsals are elongated, and the phalanges somewhat similar to those of *Dimodosaurus*. Part 9, in conclusion, briefly examines the relations of the Saurischian types with each other, and indicates ways in which they approximate towards the Ornithosauria. It is urged that the Ornithosauria are as closely related to the Saurischia as are the Aves to the Ornithischia; and that both divisions of the Saurischia approximate in *Staganolepis* and *Belodon*. Finally, a tabular statement is given of the distribution in space and time of the 25 Old World genera which are regarded as probably well established. Eight of these are referred to the Cetiosauria, thirteen to the Megalosauria, and four to the Aristosuchia or Compsognatha.—Mesosauria from South Africa, by Prof. H. G. Seeley, F.R.S.—On a new Reptile from Welte Vreden, *Eunotosaurus africanus* (Seeley), by Prof. H. G. Seeley, F.R.S. The President observed that there could be no question as to the great value of these papers, the first of which especially was the outcome of years of experience and study on the part of the author. It was only right to remark that the paper on Saurischia was received by the officers of the Society early in *April*. Since that date Prof. Marsh, in his notes on Triassic Dinosauria (which did not appear till *May* 24), had published, as regards *Zanclodon*, conclusions similar to those at which the author (Prof. Seeley) had already arrived. Mr. E. T. Newton also spoke. Prof. Seeley drew attention to a photograph of *Hortalotarsus*, a reproduction of a sketch made at Barkly East, before the original specimen had been destroyed in the process of blasting the rock.—The dioritic picrite of White Hause and Great Cockup, by J. Postlethwaite.—On the structure of the American Pteraspidian, *Palæaspis* (Claypole), with remarks on the family, by Prof. E. W. Claypole.—Contributions to the geology of the Wengen and St. Cassian strata in Southern Tyrol, by Maria M. Ogilvie, B.Sc. (Communicated by Prof. C. Lapworth, F.R.S.)—Notes on some new and little-known species of Carboniferous *Murchisonia*, by Miss Jane Donald. (Communicated by J. G. Goodchild.)—Notes from a geological survey in Nicaragua, by J. Crawford, State Geologist to the Nicaraguan Government (Communicated by Prof. J. Prestwich, F.R.S.)—Microzoa from the phosphatic chalk of Taplow, by F. Chapman. (Communicated by Prof. T. Rupert Jones, F.R.S.)—On the basalts and andesites of Devonshire, known as felspathic traps, by Bernard Hobson.—Notes on recent borings for salt and coal in the Tees salt-district, by Thomas Tate.

MELBOURNE.

Royal Society of Victoria, March 12.—Annual Meeting.—The following officers were elected for the year:—President: Prof. Kernot. Vice-Presidents: Messrs. E. J. White, H. K. Rusden. Hon. Treasurer: Mr. C. R. Blackett. Hon. Librarian: Dr. Dendy. Hon. Secretaries: Prof. Spencer, Mr. A. Sutherland.—The following paper was read:—Preliminary notice of Victorian earthworms: Part 2, the genus Perichæta, by Prof. Spencer. The author described 18 species collected in Victoria, of which 16 are new.

May 13.—The following papers were read:—On confocal quadrics of moments of inertia pertaining to all planes in space, and loci and envelopes of straight lines whose moments of inertia are of constant magnitude, by Martin Gardiner.—Further notes on the oviparity of the larger Victorian Peripatus, generally known as *P. leuckartii*, by Dr. Dendy. In this paper the author replied to some remarkable strictures recently passed upon his work by Mr. J. J. Fletcher in the Proceedings of the Sydney Linnean Society. He showed that at the time of writing his first paper on this subject nothing was known as to the method of reproduction of *P. leuckartii*, Mr. Fletcher's brief footnote to the effect that one specimen dissected was found to be pregnant not of necessity implying the presence of developed embryos within the egg-case. The Victorian specimens, containing in their uterus large eggs, might with equal truth be described as pregnant. Dr. Dendy brought forward evidence proving conclusively that in the eggs investigated by him development had gone on normally outside of the body for a period exceeding eight months, one of them at the close of this time containing a perfect young form with even the pigment developed. Since the publication of his first paper, but not prior to this, Mr. Fletcher had shown that the New South Wales *Peripatus leuckartii* was undoubtedly viviparous; and Dr. Dendy suggested that if, as seems most probable, the Victorian species is oviparous, then his original idea of its being a distinct species from the New South Wales form may probably be correct.

Paris.

Academy of Sciences, June 27.—On the local disturbances produced underneath a heavy load uniformly distributed along a straight line perpendicular to the two edges, on the upper surface of a rectangular beam of indefinite length laid down on a horizontal surface, or on two transverse supports equidistant from the load, by M. J. Boussinesq.—Contribution to the study of the function of camphoric acid, by M. A. Haller.—On the presence and the nature of the phylacogenic substance in the ordinary liquid cultivations of *Bacillus anthracis*, by M. Arloing. The liquid was carefully siphoned off from a large cultivation of the bacillus which had been allowed to stand for a considerable time. The usual porcelain filters were not employed, as they are apt to intercept most of the prophylactic substances. A liquid perfectly free from the anthrax bacillus having thus been obtained, two solutions in glycerine were prepared, the one containing the substances soluble in alcohol, the other those precipitated by alcohol. Of six lambs, two received subcutaneous injections of the former, two of the latter solution, and the rest of neither. Eight days afterwards all six were inoculated with a very virulent dose of the bacillus. The only survivors were those inoculated with the matter soluble in alcohol, thus proving that the prophylactic substance belongs to this group.—On the determination of the angle of polarization of Venus, by M. J. J. Landerer. By almost daily observations, extending from April 29 to June 8, the angle of polarization of Venus was found to vary between 45°·17 and 27°·51, using an instrument of 135 mm. aperture, to which a Cornu photo-polarimeter was adapted. The author concludes that the light from the crescent of Venus is not polarized, and hence that almost the entire visible surface of the planet is constituted by a thick layer of clouds. At the poles, however, permanent spots are observable, which are due to part of the solid surface protruding beyond the cloudy mass.—On the variations in temperature of water suddenly compressed to 500 atmospheres between 0° and 10°, by M. Paul Galopin. An account of the first of a series of experiments to be made in M. Raoul Pictet's laboratory to determine the heat produced by the adiabatic compression of a large number of liquids between − 200° and + 200°, under sudden variations of pressure amounting to 1000 atmospheres. The apparatus consists of a steel cylinder provided with a thermometer 1 m. long, capable of measuring 0°·01. Pressure is applied by means of a Cailletet pump, and the whole apparatus is immersed in a large calorimeter with quadruple envelopes. The results obtained, which vary from 0°·20 at 0°·4 to 0°·59 at 10°, show that the increase of pressure lowers the temperature of maximum density of water for that particular pressure, and that under high pressures it corresponds nearly to the freezing-point.—Measurement of the dielectric constant by electro-magnetic oscillations, by M. A. Perot. This measurement is based on the law formulated by Blondlot, according to which the period of the resonators is proportional to the square root of their capacities. The value obtained for essence of terebenthine was 2·25, that for ice between 60 and 71, in confirmation of previous results.—On the conductivity of a gas inclosed between a cold metal and an incandescent body, by M. Edouard Branly.—On the physiological effects of alternating currents with sinusoidal variations: process of administering them in electro-therapeutics, by M. A. d'Arsonval. The law indicated by the results of the experiments is that the intensity of the motor or the sensory reaction is proportional to the variation of potential at the point excited. Although oscillations of great frequency seem to have but faint physiological effects, a careful analysis shows that the absorption of oxygen and the elimination of carbonic acid in the lungs is greatly augmented.—On aluminium, by M. Balland. A series of experiments to prove that aluminium is well-suited for domestic utensils, being not more attacked by air, water, wine, coffee, milk, butter, &c., than other metals used for such purposes.—Action of chlorine on the alcohols of the fatty series, by M. A. Brochet.—On asboline (pyrocatechine and homopyrocatechine), by MM. Béhal and Desvignes.—On the vegetable cholesterines, by M. Gérard.—Researches on the adulteration of the essence of sandalwood, by M. E. Mesnard.—On two specimens of the waters of the Arctic seas, by M. J. Thoulet.—New remarks on "pœcilogony," by M. Alfred Giard.—On a sporozoarian parasite of the muscles of the Decapod Crustaceans, by MM. F. Henneguy and P. Thélohan.—The first phases in the development of certain nematoid worms, by M. Léon Jammes.—A contribution to the history of ambergris, by M. S. Jourdain.—On the *brunissure*, a disease of the vine caused by the *Plasmodiophora Vitis*, by MM. P. Viala and C. Sauvageau.—On the secretion of oxygen in the natatory vessel of the fishes, by M. Chr. Bohr.—Physiological action of mountain climates, by M. Viault. The effects of a high elevation, though powerfully beneficent for dyspeptics, neurasthenics, and tuberculous patients, must be long continued to be permanent. The effects are due to an increase in the number of blood corpuscles and in the respiratory power of the blood.—Permanent abolition of the chromogenic function of the *Bacillus pyocyaneus*, by MM. Charrin and Phisalix.

THURSDAY, JULY 14, 1892.

A TREATISE ON ZOOLOGY.

Outlines of Zoology. By J. Arthur Thomson, M.A., Lecturer on Zoology in the School of Medicine, Edinburgh. (Edinburgh and London: Young J. Pentland, 1892.)

GENERAL.—The above-named volume of 604 pages small octavo, the latest of Pentland's "Students' Manuals," is divided into twenty-five chapters, with an introduction and a well-constructed index. By way of illustration, there are interleaved two-and-thirty sheets of diagrammatic sketches. It is difficult to find upon these any dozen figures which adequately represent anything in nature, and the majority of the "diagrams" are the rudest of rude sketch maps. Archetypes are well to the fore with their misrepresentations and evil influences, and such illustrations as those of the "unsegmented worm," the "spinal canal" figure of Plate 22, and others akin to them, are meaningless atrocities, conveying absolutely no idea to the mind. The Peripatus series are very suggestive; they are three in number—namely, one (bad) depicting the whole animal, another (worse) of a nephridium, and a third (unfounded) representing a conventional branched tube, spiral lining and all (*sic*). To be brief, the illustrations are mostly bad, and might well be dispensed with. Of those copied from well-known figures, many are spoilt in the copying, while the remainder are such as might have been produced in the greatest haste by a person accustomed to reading about, but not to handling, objects of the class delineated.

The book itself is written in a clear and intelligible style, and its author has been at immense pains in producing it. He deals with many difficult topics, especially when they do not involve minute structural detail, with conspicuous success. He is in some parts racy, in others flippant, *pace* the remark (p. 264) that "even a wooden leg may crumble before" the jaws of the termite; and he occasionally shows himself to be alive to difficulties of the passing moment—for example, that of the histogenesis of the nerve fibre. Some sections of the work are deplorably meagre, *e.g.* those devoted to the Ganoids, Tunicata, Rotifera, and Sponges, and especially to the Brachiopods and Polyzoa, which (following Lang) the author ranks with the Sipunculids and Phoronis as the "Prosopygii." Classifications such as that given of the Chelonia, and the adoption of the absolutely groundless term "Ornithosauria" as the ordinal name for the Pterodactyles, are bad examples of their kind. Akin to the occasional flippancy already alluded to are the descriptions of the embryonic membranes as "birth-robes," of the crystalline lens and the liver as "moored" to adjacent structures, and of the viscera as "swathed" in the mesentery. All science worthy the name must be now technical, whether set forth in the pages of a monograph or of a text-book; and when recognized terms are in daily use they should be employed. Personal names are occasionally mentioned; and it is a curious detail that, with one or two exceptions, those of workers in the Edinburgh School are alone qualified. We strongly deprecate the mention of individuals in an elementary text-book, as unnecessary and liable to abuse; but, in having adopted the course alluded to, the author displays a becoming respect for his seniors, such as we could wish were more general nowadays. His book is written for Edinburgh students; but we nevertheless note the absence of all reference to certain organisms in vogue among them—to wit, *Trochosphæra*, a knowledge of the development of which was demanded in a recent syllabus issued by authority.

The book, however, while lacking in much that is of primary importance, contains a bulk of excellent material. It is wonderfully free of really gross errors, and we therefore willingly recommend it on its general merits as a useful work of reference, believing that the author will strengthen its weaknesses as opportunity occurs.

The assertion that *Limnocodium* was "found in a tank at Kew" will probably whet the appetite of that establishment, and statements like that of the brain being "but an anterior expansion of the medullary canal," while self-explanatory, afford at least a relief to the reviewer.

Analytical.—The author tells us in his preface that his book is "intended to serve as a manual which students of zoology may use in the lecture-room, museum, and laboratory"; and, in accordance with this, he subdivides most of the chapters each into three sections, dealing respectively with what we presume he would consider a lecture equivalent, with the more didactic consideration of type-structure, and with facts usually embodying the principles of classification. A very ambitious scheme this; and it will be convenient to deal with each of the three departments separately.

First, as to the use of the book in the laboratory. The author here deals with familiar types, and supplements these here and there by the addition of wisely chosen species. His descriptions are, however, at most points insufficient and far too general, the one detailed account being made to do duty in the case of the Simple Ascidian (p. 358) for three distinct genera. This is not as it should be. The method of laboratory instruction in zoology employed in this country, with its rigid adherence to the type-system, is, in the long run, but that of teaching the alphabet whereby the student shall read; and, even were this not so, the laboratory training is one in discipline and observation, wherefore it is of the highest importance that any notes which shall be given the beginner for his guidance in it, shall be rigidly confined to actual statements of observed fact. The author partially disarms criticism under this head by remarking that his book is intended (preface) "as an accompaniment to several well-known works," which he cites (p. 88), and among which he enumerates leading laboratory treatises. Unfortunately, however, the plan of construction of those works does away with the necessity for his own as an adjunct to their utility. And we have therefore but to deplore the incorporation of generalities and ambiguities, in a portion of the author's treatise where they are calculated to encourage a general looseness, and to nullify much of the good intended by the founders of the system which he has adopted.

On passing to the two remaining departments of the book, we express ourselves at a loss to appreciate the utility of a text-book in the lecture-room. Much that passes current for scientific lecturing nowadays is mere parrot-work; and lecturing which is confined to mere text-book recapitulation (such as could alone justify the author's intention that his book should be used in the lecture-room) is no lecturing at all, but rather a poor form of dictation work. We deem it the highest aim of a scientific lecturer to teach his hearers, by example, how best to extend, systematize, and apply their knowledge of crude facts previously acquired in the laboratory. He should in all cases work out from these and lead up to generalizations; and, to the end in view, he should be up to date in his reading, and, above all, cautious in his selection of approved topics. Given this line of action, the competent teacher could not fail to present his facts in a manner in which they could not be found in any text-book. The author of the work before us has clearly realized this position, and much of his book which we presume he would regard as the equivalent of lecture material, fulfils our ideal. We note, however, a too frequent want of judgment, and a too general desire to present theories before facts. By way of example, the inter-relationships of the Echinodermata are summarily dismissed in some ten or a dozen lines, in a manner as "cocksure" as it is certainly erroneous; and the beginner is told (p. 377) that the ribs of Vertebrates "perhaps bear the same relation to the vertebræ that the visceral arches do to the skull," before he either knows sufficiently what constitutes a rib, or at all appreciates the difficulties in the way of homologizing the ribs of the leading classes of Vertebrata. And here and there the author goes out of his way to raise difficulties at the outset (*e.g.* the opening sentence in the book, and the second sentence of p. 121), when dealing with terms having a definitely accepted meaning; while, in ushering in the Mollusca with a reference (p. 299) to "a diagrammatic summary of the chief anatomical characters" and a "schematic Archi-mollusk—a reconstruction of a possible ancestor," he proceeds along a line subversive of all good discipline established either on precedent or sound sense. There is here evidence of a topsyturveydom in method, which could only be productive of disastrous results.

Concerning the more strictly text-book portion of the volume, we confess to a similar attitude of mixed judgment. There is in it much that is admirable and beneficial, and not a little that is crooked and injurious. The gastræa theory is swallowed outright, mention of equally plausible alternative ones being confined (p. 62) to five none too fortunate lines. The description of the scapula (p. 472) as "a membrane bone," of the cranial nerves of vertebrates (p. 381) as ten in number; like the assertions (p. 444) that "it is very difficult to distinguish Amphibians from Fishes," that (p. 33) Volvox "is a hollow sphere of epithelium," that the skate's egg-purse is (p. 425) "composed of a horny substance allied to that of hair and hoof"; like definitions such as that of *Balanoglossus* and *Cephalodiscus* (p. 348) as "surviving incipient Vertebrates" (of course with a "notochord"), of *Lepidosiren* (p. 428) as "only a species of *Protopterus*," simply will not do; while arrangements such as those of the Mammalia (p. 7) and Vermes (p. 149) are hardly in keeping with modern conceptions.

Retrospective.—On retrospective examination of the book before us, we seek in vain for evidence of that impress of the author's individuality as an actual worker which has so often "made" the zoological text-book of the past. The author has been too content to abstract all in his way. Obsolete classifications are placed side by side with others as audacious as they are premature, and rival theories are alike abstracted for what they may be worth. When, however, the author's method leads to the citing (p. 86) of Kropotkin as an authority on evolution; to the placing side by side, as alternative interpretations of the phenomena of Nature, those generalized statements of facts which constitute the "laws" of Darwin, and the flighty fantasies shot at a venture by certain younger "law-makers" (some of whom are sufficiently candid to admit that they are generalizing without facts), willing to risk all if, perchance, a frivolous public will but proclaim them philosophers, the experienced naturalist, in whose hand the judgment lies, steps in and demands a reconsideration. In a word, the author has insufficiently exercised his judgment in selection of material. To the teacher of science the duty of showing his scholars, by inference, what to neglect is, perhaps, of paramount importance to that of indicating upon what they are to rely. The author of the volume under review would, however, leave the discretion in the hands of the student; he writes rather as the amateur, to whom everything is equally important, and in thus acting he fails to recognize one of the highest functions of his office, to the utter confusion, if not the ruin, of his followers. In our opinion, his book, although in many respects admirable, falls short in each of its great departments which we have signalized. It will be largely used, and we wish it an ultimate success. It nevertheless contains the framework of a really serviceable text-book; and if the author will elaborate this, using a fitting exercise of judgment, and either eliminating the illustrations altogether or replacing them in others better and more numerous, he ought to produce a work of more than passing value, and he would sufficiently justify the great pains at which he has placed himself. In its present form the book is calculated to encourage a love of premature generalization, and anyone adopting its methods would teach fantasies before facts. The mental attitude which it typifies is one apt to create a bias, under which the student would suffer in his after work, as is indeed exemplified by the author himself in his treatment (pp. 178–79) of the reproductive organs of the worm. To encourage this is but to foster a growing evil. The didactic method of instruction in zoology now in vogue will unmistakably prevail in the future; but, unless its dryness be salted with work akin to the good old-fashioned field work, to the discouragement of the more modern and pedantic phylum-mongering and striving after impossibilities, better, by far, the *régime* of the past.

G. B. H.

WATTS' "DICTIONARY OF CHEMISTRY."

Watts' Dictionary of Chemistry. Vol. III. By Forster Morley and M. M. Pattison Muir. (London: Longmans, 1892.)

THE third of the four volumes of this excellent work has just appeared, and in value and interest this one does not stand behind the two previous volumes.

Amongst the articles written by eminent specialists, one, the most important, is that contributed by Prof. J. J. Thomson, of Cambridge, on the theories of the molecular structure of bodies. It is from the interpretation of chemical phenomena, by the help of exact physical research, that we may most hopefully look for insight into the true explanation of these phenomena. And although the theory of the molecular constitution of matter now universally held has been adopted as regards chemical change ever since the publication of Dalton's new system of chemistry in 1808, the crucial proof of its necessity has only recently been given. Prof. Thomson briefly but clearly explains the historical development of this proof. The first attempt was made by Cauchy, founded on the dispersion which light experiences when it passes through transparent bodies. But this attempt was an incomplete one, and a less ambiguous proof was given by Osborne Reynolds in 1879, based upon the thermal effusion of gases. Lord Kelvin, Loschmidt, and others have gone still further, not only proving that matter possesses structure, but giving limits below which the "coarse-grainedness" of matter cannot lie. These conclusions are founded upon considerations of several distinct sets of phenomena, viz. surface-tension, the difference of potential which occurs when two metals are placed in metallic connection, the amount of polarization at the surface of an electrode and of an electrolyte, and the viscosity, the diffusion, and the conductivity for heat, of gases. The discussion of the methods by which the limit is reached in the case of surface tension is next clearly given, and the result arrived at that a thickness of 10^{-8} cm. must be comparable with the range of molecular action of the water molecules. The results of the well-known researches of Quincke on silver films and on capillary elevation, as summarized in a lecture delivered before the Chemical Society of London by Prof. Rücker in 1888, are then explained, and the limits of molecular action deduced from these experiments. Having given an idea of the coarse-grainedness of matter, Thomson proceeds to consider the various theories of that structure, and gives an account of the most important of these by Lord Kelvin and Lindemann. The evidence of molecular structure afforded by the spectra of bodies, that concerning the arrangement of the atoms in the molecule on the supposition that the atoms are vortex-rings, and the electrical theory of molecular structure, first brought forward by Helmholtz in his Faraday Lecture, are all clearly discussed; and the author's own researches on the conduction of electricity by gases, which bear out the results of this latter theory, are adverted to. The whole article, which only extends over seven pages, forms an admirable exposition of a most important, if a somewhat difficult, subject, and shows what chemistry gains from the work of mathematical physicists.

Another short but excellent article is that by Mr. Shenstone, on ozone, including, as it does, the most recent work on the subject, as well as a *résumé* of the older and better known results. The question as to the relation existing between the quantity of ozone produced and the potential difference between the discharging surfaces, does not appear to have as yet been settled, though Berthelot finds that an increase of potential produces an increased yield of ozone. Nor has the exact influence of temperature and pressure been properly made out, though it appears that at a pressure of about 50 mm. ozone is alternately produced and destroyed. These facts point to the conclusion that, although much labour has already been spent upon the investigation of ozone, much yet remains to be accomplished before our knowledge of "modified oxygen" is anything like complete.

Of the recent progress made in our general chemical conceptions, none are of greater, if any are of as great, importance as the foundation of the periodic law by Mendeleeff in 1869. A Dictionary which failed to give an account, not only of the nature of this law, but also of its rise and development, would indeed be incomplete. Mr. Douglas Carnegie's article, however, does justice to his subject, and I am glad to see he has not ignored the extensions made by my lamented pupil and friend, Carnelly, which are truly said to be as much in advance of the earlier views of Dumas and Gladstone as the periodic law is in advance of the earlier disconnected schemes of classification. And I agree with the writer in his remarks that if these extensions must be regarded as bold speculations, they indicate the direction in which investigations on the *rationale* of the periodic law, and of the nature of the elements, will probably have to be prosecuted before we can hope to arrive at any explanation of the law, or of the nature of the chemical elements themselves.

The article on "Metals (rare)" is, of course, contributed by Mr. Crookes. It contains an account of the contributor's own researches on the splitting up of the rare earth metals. Many of the metals described in our treatises, and in the Dictionary itself, are probably mixtures. Some years ago I proved that an element termed philippium was in reality a mixture of two others, viz. terbium and yttrium, and Mr. Crookes's researches have since confirmed my results. It is, however, quite true, as Crookes observes, that until we know what terbium and yttrium themselves are, we have not got to the bottom of the question. And from his own work it does not appear very likely that the chemists of this generation will bottom this subject, for the more Mr. Crookes works on the separation of these bodies the more complex does the question of identification appear to become. Those who wish to form an idea of the character of work of this kind will do well to study the article.

A notable characteristic of this Dictionary is the summation of the properties of the different allied groups of chemical elements. Thus in this volume we find an excellent article by one of the editors, Mr. Pattison Muir, on the nitrogen group of elements. The relationships between the corresponding compounds of two different members are clearly set forth in tabular form, and thus the reader is able at a glance to compare the analogies and differences which these compounds exhibit both in composition and properties.

Prof. Armstrong's article on isomerism bears out the author's reputation for clear statement and complete knowledge of his subject. He fully discusses its historical development, strengthening his statements by valuable quotations from the writings of chemists of eminence, and brings the matter up to the latest views of chemists such as Van't Hoff, Victor Meyer, Wislicenus, and others, who have recently contributed to our knowledge of isomeric bodies.

For the rest, which indeed forms the bulk of the volume, I must content myself with saying that the numerous articles descriptive of organic compounds, ranging from indin on p. 1 to phenyl-tetrazole carboxylic acid on p. 858 (not to mention the inorganic compounds) are mainly contributed by Dr. H. Forster Morley, one of the editors. How far these hundreds of compounds are adequately described, or what mistakes of omission or commission the descriptions may contain, or how many printers' errors exist, must be left to be determined, if determined at all, by someone with more leisure, and, may I add, with more taste for that sort of work than I possess. But I may conclude by saying that, knowing the accuracy and care which uniformly characterize Dr. Morley's work, I do not think that any adverse critic, if such there should be, of this great addition to our chemical literature, will find it a very happy hunting-ground, for, as far as I am able to judge, the work has been carefully and accurately done. H. E. ROSCOE.

THE ENGLISH SLÖJD.

Manual Instruction; Wood-work; the English Sloyd. By S. Barter. With 302 Illustrations. Preface by George Ricks, B.Sc.Lond. (London: Whittaker and Co., 1892.)

IT is to be regretted that the author of this very excellent and practical work should not have stated on the title-page what it really is, *i.e.* a book simply teaching carpentry, including directions for a limited amount of technical or mechanical drawing, and not have termed it "Wood-work," since by this term much is understood which is not given in his pages. Neither is there any occasion for the word which he gives in one place as *Sloyd* and in others as *Slöjd*, it being sufficiently misused already in Swedish by being confined to common incised carving and small carpenter's work, when it is properly applicable to all kinds of technical art. Since Mr. Barter has had the intelligence and boldness to declare that whatever can be done with the barbarous "*Slöjd*" knife can be better done with the chisel, it is to be regretted that, as he is with his English common-sense altogether out of and beyond *Slöjd*, he did not let the Swedish system alone altogether. There was no occasion for him to mention it or its palpable defects, to which he might have added the preposterous arrogance of its claims to be the incarnation of all that is needed to train the hand and eye to industrial art. However, since he who is fitter to be the leader humbly assumes the name, and follows the lead as an English *Slöjder*, we, of course, cannot complain, since it is to his own disadvantage that he assumes a title which detracts seriously from the merits of the treatise. He gives a very good introduction on drawing, which has, however, the serious defect of being beyond the capacity of mere boys, who, while at carpenters' work, certainly cannot be expected to devote hours to learning the meaning and application of "orthographic projection," "the assumption of the existence of parallel horizontal rays of light which project the elevation on a vertical surface," "isometric axes," and "therefore as AC is to $CH :: \sqrt{3} : \sqrt{2}$; but $CH = A'K$, which is," *et cetera*—all of which, with the diagrams, contrasts strangely with the pictures of the ten-year-old chubby youngsters who are represented as merrily sawing and planing in the frontispiece. It is true that there are little boys who can master Euclid, or its equivalents; but an experience of years in teaching qualifies us to state that a much more simply written chapter than this, or one within the ready comprehension of "boys," would have been better adapted to the book. The forty-two pages devoted to timber are thoroughly scientific, practical, and admirable. Yet as boys seldom have any great choice of wood, and have little to do with teak, ebony, and lignum vitæ, much of the space might have been better devoted to some kind of wood-work not touched on in this book. Materials and tools are well described. We observe that in his illustrations of nails Mr. Barter makes no mention of the very best of all—the triangular, which goes home as straight as a screw, and holds like one.

"Bench-work" is the best portion of the book, being thorough, comprehensive, and manifestly written by a master of the subject. It is not beyond the comprehension of an intelligent boy who will devote to it serious attention; therefore, for such as are somewhat advanced, it may be warmly commended, for the simple reason that intelligent minds pay most serious attention to, and remember best, what costs them some trouble. The author is evidently a very practical, serious, and earnest mechanic, who, understanding his business perfectly, describes everything as he would teach it to a class of young men who had been a while in workshops. But with his "orthographic projections" as with his whole style, he is—not invariably, nor even generally, but very often—too hard for urchins; and, in fact, the juvenile who is depicted on p. 175 as boring a hole has appropriately the pensive air of one who is very much bored himself—probably by some difficulty in the text. Yet all of this does not detract from the fact that the work is an admirable one, that it is the best of its kind, and perfectly adapted to the use of teachers establishing classes, who are, after all, the only persons who really need or read such works, as pupils seldom look at anything of the kind unless required to. But though it is very seldom done, it would have good results if pupils in technical schools should be made to read more, and secondly, if the teacher should carefully explain to them the text.

An excellent feature in the bench work is that the author, giving the names of a majority of such objects as an amateur may expect to make, describes in detail, with excellent and abundant illustrations, how to make them. He might in some cases have gone a little further in his work. Thus it never appears to have occurred to him that parquetry, or inlaid work, can be made save by sawing out pieces of wood in their natural colours. But a large portion of French and Italian work is made by using wood which is artificially coloured, and we should not have expected this to be passed over by a writer who had the intelligence to remark that "Colour, which plays so prominent a part in design, is entirely overlooked in he Slöjd system," which it certainly is, and with it much more that is indispensable to teaching the minor arts as a system even to the youngest children. Nor does Mr. Barter mention the so-called Venetian *intarsiatura*, in which the pattern, drawn on one piece of wood, is cut half through the panel, the line being then filled with coloured mastic, and the pattern dyed. But such sins of omission are trifling, though in a book which proclaims on its title that it is devoted to wood-work we should have expected something more than carpentry, and at least a full description of Slöjd carving. And having pointed out, as in conscience bound, every defect, we feel it to be a duty to congratulate the publishers of this remarkably handsome, well-bound, and useful work on having done their best, and on having issued a manual which deserves a place in every industrial school.

But there is a word to be said as regards the preface and a portion of the introduction. It is perfectly true that manual instruction for children develops their intellects, and fits them for life far more than ordinary school studies usually do. But it is not true that this training should consist, as Messrs. Ricks and Barter virtually declare, of nothing but Slöjd, be it Swedish or English, or of carpenters' work. Such training should be for girls as well as boys, and it should be based on design and drawing, taught simultaneously in the simplest and easiest freehand; after which the pupils may take up not merely carpentry, or even Slöjd—which is nothing effectively but a minor branch of wood-carving—but also wood-carving itself, and many other arts, all of which come as one and promptly to the pupil who can design, and, when occasion favours, also can model a little. But to expect that carpentry alone, without a trace of art, is all that is needed to inspire the creative faculty is a great mistake; and what is worse is that, despite thousands of living examples of the superiority of the more artistic method for children, the British—like the American—public persists in believing that all that is needed is to teach "our boys" how to make benches and boxes.

OUR BOOK SHELF.

Thermodynamische Studien. Von J. Willard Gibbs, übersetzt von W. Ostwald. (Leipzig: Engelmann, 1892.)

THIS is a German translation of three of Prof. Gibbs's Thermodynamic Papers. These were published during the years 1873-8, in the Transactions of the Connecticut Academy (vols. ii. and iii.); and one reason which prompted Prof. Ostwald to undertake the translation of them was their inaccessibility to the general scientific public. Their importance is sufficiently attested by the fact that part of the ground covered by Prof. Gibbs has been gone over again by later writers who deemed they were themselves pioneers.

"Graphical Methods in the Thermodynamics of Fluids" is the title of the first paper. It gives for the first time a general account of the comparative advantages of using various pairs of the five fundamental thermodynamic quantities for graphical representation. The entropy-temperature and entropy-volume diagrams are discussed in considerable detail. The second paper contains the description of the volume-energy-entropy surface, which generally goes by the name of Gibbs's thermodynamic surface. Its contents are familiar to all who have studied Maxwell's "Theory of Heat."

The third paper, "On the Equilibrium of Heterogeneous Substances," fills five-sixths (344 pages) of the whole book, and is, out of question, by far the weightiest contribution which Prof. Gibbs has made to the development of thermodynamic methods. To him must be given the credit of first formulating the energy-entropy criterion of equilibrium and stability, and developing it in a form applicable to the complicated problems of dissociation. To give anything like a complete idea of the contents of this paper, with its discussion of critical points, capillarity, growth of crystals, electromotive force, &c., would mean the reproduction of Prof. Gibbs's own very full synopsis, which in the German translation forms the greater part of the table of contents of the book. It will suffice to notice the general theory of the voltaic cell, with which the paper ends. Here distinctly for the first time is it pointed out that the electromotive force of the cell depends on other factors than the variations of its energy. Von Helmholtz's theory, which differs from that given by Prof. Gibbs only in the greater fulness of detail, was not published till 1882.

Prof. Ostwald tells us that he had the benefit of the author's revision. With the exception of a few obvious corrections the original papers are most faithfully reproduced, even to certain footnotes which in these days have no particular value. In the circumstances a little license might well have been taken, and a slavish adherence to the original text departed from. For example, it is surely most desirable to use the word *isenergic* for lines of equal energy, and not the inappropriate term *isodynamic* which Prof. Gibbs made use of in his paper of 1873. Again, we question the right of any writer on thermodynamics to use the word *reversible* in other than Carnot's sense. Such double meanings tend to produce confusion, in spite of elaborate footnotes.

These blemishes apart, however, there is no doubt that Prof. Ostwald deserves great credit for his labour of love in preparing this translation. He has made it possible for the many, who know of Prof. Gibbs's work only at second hand, to acquaint themselves with the original papers, and we feel confident that the book will find its place on the shelves of all who desire a really complete library of thermodynamic literature.

Elements of Physic. By C. E. Fessenden. (London: Macmillan and Co., 1892.)

THE subject matter of this book is arranged in four chapters—Matter and its Properties, Kinematics, Dynamics (including statics, hydrostatics, and pneumatics), and Heat. It thus forms an excellent introduction to a more extended study of physical science. The treatment of the subject is based largely on simple experiments to be performed by the student himself, whose reasoning powers the author seeks to draw out as far as possible by suggestive questions interspersed through the text. The following example will give a good idea of the style of treatment:—

". . . All experience teaches that *no two portions of matter can occupy the same space at the same time.* This property which matter possesses of excluding other matter from its own space, is called *impenetrability.* It is peculiar to matter, nothing else possesses it. These facts being known, let us proceed to put certain interrogations to nature. Is air matter? Is a vessel full of air a vessel full of nothing? Is it 'empty'? *Can matter exist in an invisible state?*

"*Experiment* 1.—Float a cork on a surface of water, cover it with a tumbler, or tall glass jar, and thrust the glass vessel, mouth downward, into the water. . . . State *how* the experiment answers each of the above questions and what evidence it furnishes that air is matter, or, at least, that air is like matter.

"*Experiment* 2.—Hold a test tube for a minute over the mouth of a bottle containing ammonia water. Hold another tube over a bottle containing hydrochloric acid. The tubes become filled with gases that rise from the bottles, yet nothing can be seen in either tube. Place the mouth of the first tube over the mouth of the second, and invert. Do you see any evidence of the presence of matter? Was this matter in the tubes before they were brought together? If not, from what was it formed? Which of the proposed questions does this experiment answer? How does the experiment answer it?"

In many cases the questions asked are beyond the powers of the average beginner to answer, but this is not a serious objection if the book is used, as seems to be intended, for class instruction in schools. For such use it is admirably well adapted. Numerous questions and examples are scattered throughout the text; in the sections of kinematics and dynamics geometrical treatment alone is adopted, the student being supposed to be acquainted with Euclid but not with trigonometry.

The style is concise, but clear and accurate, and as the book has not been written with the view of preparing the student for any special examination it is refreshingly free from any tendency towards cram. H. H. H.

Recette, Conservation, et Travail des Bois. Par M. Alheilig. (Paris: Gauthier-Villars et Fils, 1892.)

THIS little book belongs to the useful series entitled "Encyclopédie Scientifique des Aide-Mémoire." The author presents a remarkably clear summary of the principal facts relating to wood, regarded from an industrial point of view. Although iron and steel have to so large an extent taken the place of wood in various great constructions, wood is still, of course, needed in vast quantities, and instruction in the proper way of dealing with it for industrial purposes must always form an important department of technical education. M. Alheilig has supplied a good text-book, the most valuable characteristic of which is that its practical details rest on a sound basis of scientific principle. He is especially successful in the chapters on the tools and machinery used in the working of wood.

Country Thoughts for Town Readers. By K. B. Baghot de la Bere. (London: Simpkin, Marshall, and Co., 1892.)

THE greater part of this book consists of imaginary conversations between a Canon and "a city lawyer," who spends two days with him in the country. The Canon lectures his friend with an air of authority and patronage which would not be particularly agreeable to ordinary mortals. The city lawyer, however, is never tired of thanking the great man for the knowledge he communicates. The Canon's information is made up chiefly of scraps of scientific commonplace, which, if they can be of no particular service to any class of readers, are at least harmless.

A Synoptical Geography of the World. (London: Blackie and Son.)

NO effort has been made by the compiler of this handbook to present geography in an attractive form. The volume consists of a number of bald statements which, as here given, could neither excite interest nor form any real addition to knowledge. It is not intended, however, that the book shall be used apart from other means of instruction. It is meant to be taken "in conjunction with a fuller text-book or the teacher's lectures." Used in this way it may be of some service to students in the revision of their work before examination. A good many maps have been specially engraved to accompany the text.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

An Acoustic Method whereby the Depth of Water in a River may be measured at a Distance.

ABOUT two years ago, I wished to know from time to time the rate at which a river was rising after a fall of rain. The river was at a considerable distance from the spot where its height was to be known. By means of the combination of two organ pipes, and a telephonic circuit, described in the following lines, I have been able to make the required measurement within rather close limits. At the river station, an organ pipe was fixed vertically in an inverted position, so that the water in the river acted as a stopper to the pipe, and the rise or fall of the water determined the note it gave, when blown by a small bellows driven by a very small water-wheel. A microphone was attached to the upper end of the organ pipe; this was in circuit with a wire leading to a town station at some distance; at the town station there was an exactly similar organ pipe, which could be lowered into a vessel full of water while it was sounding. By means of the telephone the note given by the pipe at the river was clearly heard at the town station; then the organ pipe at this station was lowered or raised by hand until it gave the same note. The lengths of the organ pipes under water at the two stations were then equal, so that the height of the water in the distant river was known.

The determination can be made in less than a minute by any one who can recognize the agreement of two similar notes. The arrangement when first tested was so placed that the height of water at two places near together might be easily compared. I found that a lad with an average ear for musical sounds was able to get the two heights to agree within one-eighth of an inch of each other, while a person with an educated ear adjusted the instrument immediately to almost exact agreement. The total height to be measured was 17 inches. A difference of temperature at the two stations would make a small difference in the observed heights. For example, taking a note caused by 250 vibrations per second, a difference of 10° C. between the temperatures of the two stations (one not likely to occur) would make a difference of about 0·02 feet in the height, a quantity of no moment in such a class of measurements. The organ pipes were of square section, and made of metal to resist the action of the water.

FREDERICK J. SMITH.

Trinity College, Oxford, June 28.

Waterspouts in East Yorkshire.

ON June 9, 1888, a waterspout was seen traversing the Yorkshire wolds in the neighbourhood of Langtoft, which finally spent its fury on the north-eastern side of a large basin-like range of valleys, where a steep declivity barred its further progress. A single cutting or trench was made in a slight hollow of the hill, and in this three large holes were scooped out of the chalk, which was here composed of much rubble, about seven feet in diameter and depth.

On July 3 of the present year, another waterspout has been developed, and has again expended its energy on the same hill as the previous one in 1888, a few yards only further south of the former site, and, taking a trifle more easterly course, has cut three parallel ditches or elongated pits in the solid chalk, two of them twenty to thirty yards in length, and seven to ten feet deep in the deepest portions, scattering the whole of the expelled rock, amounting to many tons, to the foot of the hill.

Serious floods were consequent, and the village of Langtoft, which is situated lower down the valley, was terribly inundated with a volume of water seven to ten feet in height, an immense amount of damage being done, including the total demolition of two cottages and a workshop. Fortunately no lives were lost beyond several pigs, sheep, and a few hundred fowls.

Driffield, July 9. J. LOVEL.

On the Line Spectra of the Elements.

PROF. STONEY seems to agree with me that I have given an obvious example of a motion for which the theorems in chapter iv. of his memoir do not hold good. Theorem B, page 591, runs thus: "Any motion of a point in space may be regarded as the co-existence and superposition of one *definite* set of partials which are the pendulous elliptic motions determined as above, &c." It is indeed obvious that a uniform motion in a straight line cannot be regarded in this manner, not even approximately for any length of time, if the set of partials are required to be *definite*. I might have given an example of a limited motion, *e.g.* $x = \sin t^2$, which equally contradicts the theorem, but I thought a more obvious example would convince Prof. Stoney more easily. I think, indeed, that the reasoning in chapter iv. of his memoir is erroneous. But I do not say that therefore Prof. Stoney's views on the cause of the line-spectra are wrong. They may be right, although the argument in chapter iv. is not. Why this criticism is not legitimate I do not see. For no slight alterations or additions would set those theorems right, as there is a palpable mathematical error at the bottom of it.

Technische Hochschule, Hanover, July 9. C. RUNGE.

The Grammar of Science.

THE exposition of the Newtonian laws as given by Thomson and Tait has unfortunately been taken as the basis for the treatment of the laws of motion by all elementary text-book writers in the English tongue since the publication of the great "Treatise on Natural Philosophy." When that exposition is attacked we are told that Newton introduced a qualifying context which has been omitted from the exposition. In other words the current statement of elementary dynamical principles is thrown overboard in favour of Newton pure and simple. On the other hand when Prof. Tait uses an expression which is totally opposed to that principle of the "subjectivity of force" which C.G.K. claims that Prof. Tait was the first, or among the first, to propound, we are told that this expression was obviously suggested by "Newton's own anthropomorphic language." C.G.K., I take it, admits that the Newtonian Laws of Motion are illogical and unphilosophical when stated by Thomson and Tait without Newton's modifying context. I propose therefore to shortly publish a criticism of the laws of motion as accompanied by that context of Newton's which does not appear in Prof. Tait's text-books. I trust C. G. K. will not then turn round on me and say, "Oh, yes, but this has nothing to do with Prof. Tait; it is Newton's own anthropomorphic language."

Lastly, as to the origin of the doctrine of the "subjectivity of force," which to my mind is just as much or as little valid as the "subjectivity of matter," I would remind C. G. K. that the first two parts of Kirchhoff's "Mechanik" were published in 1874, and were then only the publication of lectures of an earlier date. Philosophers before Kirchhoff taught the doctrine of subjectivity, but he, and not the author of the "Dynamics of a Particle," was the physicist who first helped many of us out of the mental obscurity as to dynamical principles produced by our study of the expositions of the laws of motion due to the Edinburgh school. KARL PEARSON.

"Are the Solpugidæ Poisonous?"

IN reference to this question, propounded by Mr. Bernard in your last issue, I should be inclined to answer in the negative. I captured several specimens of *Solpuga chelicornis* in the Transvaal, and on one occasion witnessed a persistent attack made on this "spider" by a bird which appeared to be the Cape wagtail (*Motacilla capensis*). Had the *Solpuga* possessed poisonous qualities the attack would probably not have been made.

The specimens taken by myself exhibited no signs of pugnacity, but always sought refuge in headlong flight to the nearest cover. W. L. DISTANT.

Russell Hill, Purley, Surrey, July 8.

Hairlessness of Terminal Phalanges in Primates.

I OBSERVE that, in your report of the proceedings of the Zoological Society, you allude to my paper on "a seemingly new diagnostic feature of the order Primates," viz. that the terminal phalanges are destitute of hair.

Since the paper was read I have found that this feature is not of ordinal value. But it is of sufficiently general occurrence to merit inquiry touching its distribution in different species.

Therefore I have withdrawn publication of the paper for the present. GEORGE J. ROMANES.

Oxford, July 1.

Mental Arithmetic.

REFERRING to the articles on "Mental Arithmetic" in NATURE, vol. xlv. p. 78 and 198, I beg to state that there also exists a very clearly written little text-book on arithmetic founded entirely on the principles mentioned by Mr. Clive Cuthbertstone. The title is "Neuer Unterricht in der Schnellrechen-Kunst," by C. Jul. Giesing, Editor, Carl Schmidt, in Doebeln (Saxony). Price 1 mark 80 pf. G. DAEHNE.

Dresden-Blasewitz, "Isis," July 9.

Jackals.

THE incident of the jackals entering Howrah brings to my memory that this winter jackals entered the suburban town of Bournabal, in the Smyrna district of Western Asia Minor. This last winter being severe, it was noticed in the papers that rabies had extended to wolves and jackals, and to this circumstance was attributed their entering the villages and attacking people, and also their attacking the domestic animals.

HYDE CLARKE.

WEIGHT.

THE following remarks are presented with the object of reducing the increasing gap which is growing between the treatment of the fundamental ideas of Dynamics, as taught in our academical text-books from the standpoint of verbal abstraction, and the ideas and language of those who have to deal with the actual phenomena of Nature as a reality.

1. According to the precise legal definitions of all our successive Acts of Parliament on "Weights and Measures," the *weight* of a body is the quantity of matter in the body, as measured out by the operation of weighing it in the scales of a correct balance.

The body to be weighed is placed in one of the scales, and is equilibrated by standard lumps of metal, stamped as pound weights, or kilogramme weights, or hundred weights, or ton weights, and the sum of these weights is called the *weight* of the body.

In the words of the Act of Parliament, 18 and 19 Victoria, c. 72, July 30, 1855, the British pound weight is defined as a weight of platinum, marked P.S., 1844, 1 lb., deposited in the Office of the Exchequer; and the Act goes on to say that this lump of metal "shall be the legal and genuine standard measure of weight, and shall be and be denominated the Imperial Standard Avoirdupois Pound, and shall be deemed to be the only standard of weight from which all other weights and all other measures having reference to weight shall be derived, computed, and ascertained, and one equal seven thousandth part of such pound avoirdupois shall be a grain, and five thousand seven hundred and sixty such grains shall be and be deemed a pound troy."

In defining the unit of length, the standard yard, the temperature must be defined, 62° F. in the Act of Parliament; but in defining the pound weight, there is in the Act no mention of temperature, height of barometer, height above sea-level, latitude, longitude, date and time of day, establishment of the port, &c., or of any other cause tending to alter the local value of g.

Details of the temperature and density of the air are only required when defining the volume of the gallon of 10 lbs. of water, or when making accurate copies of the standard platinum pound weight in some other metal—brass or iron, for instance—when a correction for the buoyancy of the air must be made; and it is to cover this detail that the words *in vacuo* have been added in the most recent Acts of Parliament on "Weights and Measures" (41 and 42 Victoria, 1878).

2. We now pass on to the investigation of the motion set up in a body of given weight due to the action of specified forces; we use the word *weight* advisedly, so as to agree with the terminology of the Acts of Parliament.

As the field of force in which we live is that due to the attraction of the Earth, it was natural to begin by taking the attraction of the Earth on our standard weight as the unit of force; and we find that in all Statical problems of architecture and engineering the unit of force employed is the force with which a pound weight, or a kilogramme weight, or a ton weight, is attracted by the Earth.

The engineer calls these forces the force of a pound, of a kilogramme, or of a ton; he does not add the word weight, reserving the word *weight* to denote the quantity of matter in the body which is acted upon, in accordance with the language of the Act of Parliament on "Weights and Measures."

In the Dynamics of bodies on the surface of the Earth, the same gravitational unit of force is universally employed in practice; and now, to take a familiar problem, we may investigate the motion of a train, weighing W tons, on a straight level railway, pulled by an engine exerting a tractive force of P tons, by the bite of the driving wheels on the rails.

Neglecting passive resistances, and the *rotary inertia* of the wheels, the train will acquire from rest a velocity v feet per second in s feet, given by

$$Ps = \frac{Wv^2}{2g} \text{ (foot-tons).}$$

The velocity growing uniformly, the average velocity will be half the final velocity v; so that if the train takes t seconds to go the first s feet,

$$s/t = \tfrac{1}{2}v,$$

and

$$Pt = \frac{Wv}{g} \text{ (second-tons).}$$

The word *second-tons* has been formed by analogy with the word *foot-tons*, to express the product of a force of P tons and t seconds, the time it acts; just as foot-tons expresses the product of a force of P tons and s feet, the distance through which it acts.

While Ps, the *work* in foot-tons done by the force P tons acting through s feet, has a mechanical equivalent, $\frac{Wv^2}{2g}$, called the *kinetic energy* of the train in foot-tons; so Pt, which we may call the *impulse* in second-tons of the force P tons acting for t seconds, has a mechanical equivalent $\frac{Wv}{g}$, the *momentum* communicated to the train in second-tons.

We merely state these theorems, with the addition of the proposed new name of *second-tons*, as these theorems are found in all dynamical treatises, being direct corollaries of Newton's Second Law of Motion.

We have measured W and P in tons, as would be natural in any railway-train problem, but the same equations of course hold when W and P are given in cwt., pounds, kilogrammes, or grammes; and then impulse or momentum will be given in second-cwt., second-pounds, second-kilogrammes or second-grammes; while work or kinetic energy will be given in foot-cwt., foot-pounds, or metre-kilogrammes, or centimetre-grammes, on changing to the metre or centimetre as metric unit of length, and changing at the same time the numerical measure of g.

3. The presence of g in the denominator of W in the dynamical equations will be remarked, and this constitutes a difficulty to the student, which our teachers of Dynamics have done their best to obscure.

The quantity g makes its appearance, not because W/g is an invariable quantity, as is generally taught, but because the unit of force in which P is measured is variable, being proportional to the local value of g.

With a foot and second as units of length and time, we may take the value of g at the equator as 32, increasing gradually to about one-289th part more, or about ⅓ per cent. greater at the poles, in consequence of the Earth's rotation.

The force of a pound, meaning thereby the force with which the Earth appears to attract a pound weight, is thence about ⅓ per cent. greater at the poles than at the equator; and this does not allow for the increase in g due to the ellipticity, which by Clairaut's theorem would make the total increase about ½ per cent.

But to say that a body has gained in weight one-289th part, or ⅓ per cent., in going from the equator to the pole is absurd and misleading; for if we carry our standard weights and scales with us, we shall find that the body weighs exactly the same.

When the theorist tells us that a body gains or loses one-289th part of its weight in being taken from the equator to the pole, or back again, he means that the indications on a spring balance, graduated in latitude 45° by attaching standard weights, will be about ⅙ per cent. in error at the equator and at the poles.

But such a spring balance would be illegal if used according to its graduations in any other latitude than the one in which it was constructed; and the user would lose in all cases; he would lose at the equator by selling ⅙ per cent. too much by weight; and he would lose at the poles the fines incurred from the Inspector of Weights and Measures, who would test his spring balance by attaching standard weights, composed of lumps of metal.

The spring balance graduated in latitude 45°, and employed alternately at the equator and the pole, is equivalent to a beam balance, of which the beam stretches over a quadrant of the meridian of the Earth from the equator to the pole, with a fulcrum in latitude 45°, but such an abnormal balance is not contemplated in the Act.

4. If we could transport ourselves to the surface of the Moon, Sun, or any planet, with our weights and scales, Newton's Law of Universal Gravitation teaches us that we should still find the body of exactly the same weight in the balance, the attraction of the Moon, Sun, or planets on the body and on the weights being still equal.

The magnitudes of these equal attractions would, however, have changed, since the attraction is proportional to the local value of g; on the surface of the Moon it is calculated that g is about 5·4; on the surface of the Sun it is about 30 times the value on the surface of the earth, while on Jupiter it is calculated that g is about 71.

These values of g are inferred from observation of the diameter of the celestial body, and from its weight, measured in terms of the weight of the Earth, or using the Earth as the standard weight; and calculated by Kepler's Third Law from the period and distance of a satellite, compared with the period and distance of our satellite, the Moon.

The weight of the Earth itself is inferred from the Cavendish Experiment, in which the attraction of gravitation between two given weights is measured.

According to Newton's Law of Universal Gravitation, the attraction between two spherical bodies, arranged in spherical strata, the Sun and Earth for instance, weighing S and E g (grammes) when their centres are a cm apart, will be proportional to SEa^{-2}; with C.G.S. units, this attraction may be expressed as CSEa^{-2} dynes, and then C is called the *constant of gravitation;* and the Cavendish experiment is devised for the purpose of measuring C.

Denoting by g the acceleration of gravity (in C.G.S.

spouds), then on the surface of the Earth we may take, in round numbers,

$$g = \mathrm{CE}/\mathrm{R}^2, \text{ or } \mathrm{CE} = g\mathrm{R}^2,$$

R denoting the radius of the Earth in cm, taken as $10^9 \div \frac{1}{2}\pi$, the quadrant being 10^9 cm.

With mean density ρ, the weight of the Earth, E, in g, is given by

$$\mathrm{E} = \tfrac{4}{3}\pi\rho\mathrm{R}^3,$$

so that

$$\tfrac{4}{3}\pi\mathrm{RC}\rho = g,$$

or

$$\mathrm{C}\rho = \tfrac{3}{8}g \times 10^{-9};$$

so that ρ is known from C, and *vice versâ*.

For instance, with $\rho = 5{\cdot}5$, and $g = 981$,

$$\mathrm{C} = 10^{-8} \times 6{\cdot}688.$$

We are awaiting with great interest the quantitative results of Mr. C. V. Boys, with his improved form of apparatus; but meanwhile we may take a mean density of 5·5, the mean of Cornu's and Poynting's results, which is about half the density of lead. It is very extraordinary that this should agree so exactly with Newton's conjecture, *Principia*, lib. iii., prop. x. :—"Unde cum terra communis suprema quasi duplo gravior sit quam aqua, et paulo inferius in fodinis quasi triplo vel quadruplo aut etiam quintuplo gravior reperiatur: verisimile est quod copia materiæ totius in Terra quasi quintuplo vel sextuplo major sit quam si tota ex aqua constaret; præsertim cum Terram quasi quintuplo densiorem esse quam Jovem jam ante ostensum sit."

5. A short numerical calculation will now give us the *weight* of the Earth (Hamilton, "Lectures on Quaternions"); also of the Moon, Sun, &c.

We assume that the Earth is a sphere, whose girth is 40,000 kilometres, so that R, the radius of the Earth, is $10^7 \div \frac{1}{2}\pi$ m (metres), and the volume, V, is $\frac{4}{3}\pi\mathrm{R}^3$ m³, while the weight, E, is ρV t (metric tonnes of 1000 kg, or 2205 lbs.), where $\rho = 5{\cdot}5$.

Four-figure logarithms will suffice for our calculations; and now

$$\begin{aligned}
\log 10^7 &= 7{\cdot}000 \\
\log \tfrac{1}{2}\pi &= {\cdot}1961 \\
\log \mathrm{R} &= 6{\cdot}8039, \quad \mathrm{R} = 10^6 \times 6{\cdot}366 \text{ m}, \\
\log \mathrm{R}^3 &= 20{\cdot}4117 \\
\log \tfrac{4}{3}\pi &= {\cdot}6221 \\
\log \mathrm{V} &= 21{\cdot}0338, \quad \mathrm{V} = 10^{21} \times 1{\cdot}081 \text{ m}^3, \\
\log \rho &= {\cdot}7404 \\
\log \mathrm{E} &= 21{\cdot}7742, \quad \mathrm{E} = 10^{21} \times 5{\cdot}946 \text{ t},
\end{aligned}$$

or 6×10^{21} metric tonnes in round numbers.

The weight of the Moon, M, generally taken as one-80th of the Earth, will be $10^{19} \times 7{\cdot}432$ t.

To determine S, the weight of the Sun, we employ Kepler's Third Law, which gives

$$\frac{\mathrm{S} + \mathrm{E} + \mathrm{M}}{\mathrm{E} + \mathrm{M}} = \frac{n^2a^3}{n'^2a'^3},$$

where n, n' denote the mean motions of the Sun and Moon, and a, a' their mean distances from the Earth.

Since M is insignificant compared with E, and E compared with S, we may write this

$$\frac{\mathrm{S}}{\mathrm{E}} = \frac{n^2a^3}{n'^2a'^3},$$

where $n'/n = 13$, the number of lunations in a year, and $a/a' = 390$, the ratio of the mean distances of the Sun and the Moon, this being the ratio of 57′ to 8″·8, the inverse ratio of the parallaxes.

Now

$$\begin{aligned}
\log a/a' &= 2{\cdot}5911 \\
\log (a/a')^3 &= 7{\cdot}7733 \\
\log (n'/n)^2 &= 2{\cdot}2279 \\
\log \mathrm{S/E} &= 5{\cdot}5454, \quad \mathrm{S/E} = 351{,}100;
\end{aligned}$$

so that the weight of the Sun is about 350,000 times the weight of the Earth, or about 2×10^{27} t, or 2×10^{33}g.

To determine the value of G the acceleration of gravity on the surface of the Sun, compared with g, the value on the surface of the Earth, we have

$$\frac{\mathrm{G}}{g} = \frac{\mathrm{S}}{\mathrm{E}}\left(\frac{\text{diameter of earth}}{\text{diameter of sun}}\right)^2 = \frac{\mathrm{S}}{\mathrm{E}}\left(\frac{8{\cdot}8}{960}\right)^2,$$

since the apparent semi-diameter of the Sun as seen from the Earth is about 960″, while the apparent semi-diameter of the Earth as seen from the Sun, in other words the solar parallax, is taken as 8″·8.

Now

$$\begin{aligned}
\log 960 &= 2{\cdot}9823 \\
\log 8{\cdot}8 &= {\cdot}9445 \\
\log (960 \div 8{\cdot}8) &= 2{\cdot}0378 \\
\log (960 \div 8{\cdot}8)^2 &= 4{\cdot}0756 \\
\log \mathrm{S/E} &= 5{\cdot}5454 \\
\log \mathrm{G}/g &= 1{\cdot}4698, \quad \mathrm{G}/g = 29{\cdot}49.
\end{aligned}$$

6. According to Newton's Law of Universal Gravitation, the operation of weighing out the quantity W in the balance gives the same result wherever the operation is carried out in the universe, assuming that the balance and the body to be weighed are of ordinary moderate dimensions.

It is otherwise with the quantity denoted by P, because the magnitude of the gravitation unit of force varies, being proportional to the local value of g.

Suppose we write the first two equations

$$\mathrm{P}gs = \tfrac{1}{2}\mathrm{W}v^2, \quad \mathrm{P}gt = \mathrm{W}v,$$

and now put $\mathrm{P}g = \mathrm{Q}$; this is equivalent to taking a new unit of force, $1/g$th part of the former unit; this is an invariable unit.

Now our dynamical equations become

$$\mathrm{Q}s = \tfrac{1}{2}\mathrm{W}v^2, \quad \mathrm{Q}t = \mathrm{W}v,$$

from which g has disappeared.

The first suggestion of the change to this new absolute unit of force is due to Gauss, who found the necessity of it when comparing records of the Earth's magnetic force, made at different parts of the Earth's surface, and all expressed in the local gravitation unit.

It is curious that this suggestion of an absolute unit of force, the same for all the universe, did not originate with the astronomers; but Astronomy remains mere Kinematics until an accurate determination of the Gravitation Constant has been made.

On the F.P.S. (British foot-pound-second) system, this absolute unit of force is called the *poundal*, a name due to Prof. James Thomson; so that

$$\mathrm{Q}s = \tfrac{1}{2}\mathrm{W}v^2 \text{ (foot-poundals)}, \quad \mathrm{Q}t = \mathrm{W}v \text{ (second-poundals)}.$$

On the C.G.S. (Metric centimetre-gramme-second) system, this absolute unit of force is called the *dyne*, the centimetre-dyne of work being called the *erg*, and the second-dyne of impulse being called the *bole*; and now

$$\mathrm{Q}s = \tfrac{1}{2}\mathrm{W}v^2 \text{ (ergs)}, \quad \mathrm{Q}t = \mathrm{W}v \text{ (boles)}.$$

These absolute units are always employed in the statement of dynamical results in Electricity and Astronomy, where cosmopolitan interests are considered.

7. The disappearance of g from the dynamical equations is such a comfort to the algebraist, that he now makes a new start *ab initio* in dynamics, and gives a new definition of the absolute unit of force.

He defines the *poundal* as the force which, acting on a pound weight, makes the velocity grow one foot per second every second; and he defines the *dyne* as the force which, acting on a gramme weight, makes the velocity grow one centimetre per second every second; and now if W lbs. or g is acted upon by a force of Q poundals or dynes, the acceleration a is given by

$$a = \mathrm{Q/W} \text{ (\textit{celoes} or \textit{spouds})},$$

and

$$\mathrm{Q} = \mathrm{W}a,$$

leading to the original equations

$$\begin{aligned}
\mathrm{Q}s &= \tfrac{1}{2}\mathrm{W}v^2 \text{ (foot-poundals or ergs)}, \\
\mathrm{Q}t &= \mathrm{W}v \text{ (second-poundals or boles)}.
\end{aligned}$$

These definitions of the absolute unit of force are very elegant and useful so long as we confine ourselves to calculations on paper, but they will not satisfy legal requirements. There is no apparatus in existence which will measure a *poundal* or *dyne* from these academic definitions within, say, 10 per cent. For accurate definition we must return to the old gravitation measure, and define the *poundal* or *dyne* as one-gth part of the force with which the Earth attracts a pound weight or a gramme weight, the value of g (in celoes or spouds) being determined by pendulum observations; and now the standard weight and the value of g are capable of measurement to within, say, one-100th per cent., an accuracy sufficient to prevent litigation.

In the recent report of the Committee on Electrical Standards we find the *ohm* defined as the equivalent of a velocity of ten million metres (one quadrant of the Earth) per second, to satisfy theoretical requirements; but as this definition would be useless for commercial purposes, Dr. Hopkinson insisted that it was essential that an alternate definition should be given, legalizing certain bars of metal as standard ohms.

In converting absolute and gravitation measure, we must notice that there are, strictly speaking, three different g's in existence: (1) the g of pure gravity of a body falling freely; (2) the g determined by a plumb-line, or by a Foucault pendulum of which the plane of oscillation is free to rotate; (3) the g determined by a pendulum oscillating in a fixed vertical plane, about a fixed axis; this is the legal g, so to speak, although practically undistinguishable from the g given in (2).

Sir W. Thomson's Standard Electrical Balance Instruments are graduated in gravitation measure, so that, if calibrated at Glasgow, they are one-25th per cent. in error in London, and about one-7th per cent. in error at the equator, and a corresponding correction must be made.

An absolute Spring Balance instrument would possess a spurious absoluteness, in consequence of the deterioration of temper of the spring, and of its variation of strength with the temperature, as experienced in the Indicator.

8. There is no advantage or gain of simplicity by the use of absolute units in dynamical questions concerning motion which is due to the gravitational field of force; the only change being the removal of g from the denominator on the right hand side of our dynamical equations to the numerator on the left-hand side.

For this reason engineers and practical men invariably employ the gravitation unit of force in the dynamical questions which concern them; measuring, for instance, their forces in pounds, pressures in pounds per square foot or square inch, while at the same time measuring the quantity of matter in the moving parts by pound weights.

The absolute unit of force has only recently made its way into dynamical treatment, principally in consequence of the development of Electricity. Previously the gravitation unit was universally employed, with the consequence that W in the equations of motion always appeared qualified by a denominator g, in the form W/g.

9. Noticing that W never appeared alone, but always as $\frac{W}{g}$ (for instance, that if a celoes is the acceleration which a force of P pounds causes in a weight of W lbs., then

$$P = \frac{W}{g}a, \text{ or } a = \frac{P}{\frac{W}{g}}),$$

early writers on Dynamics were unfortunately tempted to make an abbreviation in writing and printing, by replacing $\frac{W}{g}$ by a single letter M; so that the dynamical equations could be printed

$$P = Ma \text{ (pounds)},$$
$$Ps = \tfrac{1}{2}Mv^2 \text{ (foot-pounds)},$$
$$Pt = Mv \text{ (second-pounds)},$$

each occupying one line of print.

This quantity M was variously called the *mass* of the body—a quantity *sui generis*—the *massiveness* of the body, the *inertia*, or the *invariable quantity of matter* in the body.

But if M denotes the invariable quantity of matter, we have this awkwardness, that M, the invariable quantity, is measured in terms of a variable unit, g pounds; while the force P, which varies with g, is always measured by means of a definite lump of metal, the pound weight.

This awkwardness is rectified if we change the unit of force, and measure P in absolute units, poundals, and M in lbs., but now M becomes the same as W, formerly; and its introduction only causes confusion, because M is still taken by most writers on Dynamics as defined by

$$M = \frac{W}{g};$$

thus making $W = Mg$, the source of all the confusion in our dynamical equations.

If weight W is measured in pounds, as the Act of Parliament directs, and if the unit of mass is one pound, so that M is also measured in pounds, then, if W and M refer to the same body, $W = M$, and not Mg.

If $W = Mg$, and W is measured in lbs., then M is measured in units of g lbs., a variable unit, unsuitable for a cosmopolitan question.

But if $W = Mg$, and M is measured in pounds, then weight W is measured in units of one-gth part of a pound, or *poundals*, which is illegal according to the Act on Weights and Measures, c. 19, 41 and 42 Victoria: "Any person who sells by any denomination of weight or measure other than one of the imperial weights or measures, or some multiple or part thereof, shall be liable to a fine not exceeding forty shillings for each such sale."

10. The theoretical writer overrides these difficulties by giving a new definition of Weight, not contemplated or mentioned in the Act of Parliament:

"The weight of a body is the force with which it is attracted by the Earth."

Let us examine this definition closely.

In the first place, it does not appear to contemplate the use of the word *weight*, except in reference to bodies on or near the surface of the Earth.

According to this definition, what is the weight of the Moon, or of a body on the Moon? Must the Moon be brought up to the surface of the Earth in fragments, or must the weight be estimated at the present distance of the Moon?

What, again, is the weight of the Sun, or of a body on the Sun? and what is the weight of the Earth itself?

And what does Sir Robert Ball mean when he writes that "the weight of Algol is about double the weight of the Sun"?

Considering, however, merely bodies of moderate size on the surface of the Earth, the attraction of pure gravity of the Earth is only to be found in a body falling freely; the tension of a thread by which a body is supported is influenced by the rotation of the Earth.

Again, the local value of g is, theoretically speaking, influenced by the position of the Moon and Sun; it is true that the influence is insensible on the plumb-line, although manifest on such a gigantic scale in its tide-producing effects.

Suppose, then, we employ the gravitation unit of force in the theorist's definition of the weight of a body. The definition now becomes an inexact truism asserting that the Earth attracts W lbs. with a force of W pounds, and inexact, because it neglects the discount in g due to the rotation of the Earth; and to say that "the weight of a body is the force with which it is attracted by the Earth" conveys no additional information.

Having introduced the word *mass*, primarily as a mere abbreviation in printing, and having subsequently changed the unit of mass so as to make the mass the same as the weight, the theorist is now trying to dislodge the word *weight* from its primary meaning, which it has possessed for thousands of years, as meaning the quantity of matter in a body, and is trying to degrade it into a subsidiary position, to express a mere secondary idea, the attraction of gravity; and that only on the surface of the earth, and even then not clearly defined.

We might as well define the pound sterling by its purchasing power in any locality, instead of by its proper definition as a certain quantity of gold.

11. So long as the gravitation unit of force alone was employed, the same number, which expressed the number of the weights which equilibrate the body, also expressed the number of pounds of force with which the Earth appeared to attract the body; and it is only in this sense that the weight of a body is "the force with which it is attracted by the Earth"; it is essential that the unit of force should be the gravitation unit, when this definition is employed.

We say, for instance, in Hydrostatics, that a ship is buoyed up by the water with a force equal to the weight of the displaced water, which is also equal to the weight of the ship, when in equilibrium.

Again, the head of water which will produce a pressure of 150 lbs. on the sq. inch, is always

$$150 \times 144 \div 62{\cdot}5 = 345{\cdot}6 \text{ feet},$$

whatever the local value of g; the numerical measure is always the same, although the amount may differ in consequence of the variation of g and the unit of force. A boiler tested to 150 lbs. on the square inch is tried one-25th per cent. more severely in Glasgow than in London. This variation, at most $\frac{1}{2}$ per cent., is not likely to lead to litigation—*De minimis non curat lex.*

There is no particular harm in the use of the word *mass*, provided it is always measured in the standard units of weight; there is this drawback, that there is no verb to "mass"; we can say that the body weighs W lbs., but we cannot say it "masses" M lbs.

Again, the Acts of Parliament do not regulate "Masses and Measures," but "Weights and Measures," "Poids et Mesures," "Maasse und Gewichte," "De Ponderibus et Mensuris."

The French language possesses the two words *Poids* and *Pesanteur*, both of which we translate by Weight.

Poids may be translated *mass*, or quantity of matter, *copia materiæ*; but that does not justify the degradation of *weight* down to the meaning of *pesanteur*, and that merely the *pesanteur* on the surface of the Earth; having already invented *mass*, the theorist must invent a new word to translate *pesanteur*; the word *heft* has been suggested, but the word *weight* must be left alone, to do double duty occasionally.

A libellous story of the Hudson Bay Company says that in their former dealings with the Red Indians, the weight of the factor's fist was always one pound; a good illustration of weight as meaning both *poids* and *pesanteur* to ignorant minds.

An amusing instance of the confusion of using *weight* in the double sense of *poids* and *pesanteur*, when not restricted to the provincial gravitation unit of the surface of the Earth, on which the human race is imprisoned, occurred in a lecture last year on Popular Astronomy. To illustrate the fact that g on the surface of the Sun is about 30 times greater than it is here (§ 5), the lecturer said, "An ordinary middle-aged man of this audience, if transported to the surface of the Sun, would *weigh about two tons*; but his reflections on this difficulty would be cut short by the immediate prospect of being converted into *two tons of fuel*."

12. Maxwell unfortunately lent his powerful aid to the attempt to degrade the word *weight* to mean merely *pesanteur*.

In a review of Whewell's "Writings and Correspondence," edited by Todhunter, Maxwell writes that—

"Finding the word weight employed in ordinary language to denote the quantity of matter in a body, though in scientific language it denotes the tendency of that body to move downwards, and at the same time supposing that the word mass in its scientific sense was not sufficiently established to be used without danger in ordinary language, Dr. Whewell endeavoured to make the word weight carry the meaning of the word mass. Thus he tells us that—the weight of the whole compound must be equal to the weight of the separate elements."

"It is evident that what Dr. Whewell should have said was—the mass of the whole compound must be equal to the sum of the masses of the separate elements."

But Whewell was quite right, because, at the time he wrote, mass was merely the printer's abbreviation for

$$\frac{W}{g}.$$

"We are reminded by Mr. Todhunter that the method of comparing quantities by weighing them is not strictly correct." (Compare this statement of Todhunter with that of Dr. Harkness in his article on "The Art of Weighing and Measuring," NATURE, August 15, 1889, p. 381, where it is pointed out that weighings can be carried out to within one 10-millionth part.)

Again, in Maxwell's "Theory of Heat" (p. 85), we read "In a rude age, before the invention of means for overcoming friction, the weight of bodies formed the chief obstacle to setting them in motion. It was only after some progress had been made in the art of throwing missiles, and in the use of wheel-carriages and floating vessels, that men's minds became practically impressed with the idea of mass as distinguished from weight. Accordingly, while almost all the metaphysicians who discussed the qualities of matter, assigned a prominent place to *weight* among the primary qualities, few or none of them perceived that the sole unalterable property of matter is its *mass*."

The question in dispute resolves itself, then, merely into a difference of terminology; and the metaphysicians are using the language universally employed up to the middle of this century, and are justified on all sides in their usuage: Maxwell might as well have criticized the traditional names which astronomers employ for the heavenly bodies.

Maxwell would even have edited the authorized and revised version of the New Testament; in *ὡσεὶ λίτρας ἑκατόν*—translated "about an hundred pound *weight*"—(John xix. 39), he proposed the omission of *weight*, probably inserted in the version to make a distinction from pounds *sterling*.

This addition of the word weight is common elsewhere, thus, "His Majesty's Warrant, August 19, 1683, to cause 3 barrels of fine pistol powder, 3 cwt. weight of pistol bullets, and 3 cwt. weight of match to be delivered to John Leake, Master Gunner, for the use of the 3 troops of Granadiers, &c." ("Notes on the Early History of the Royal Regiment of Artillery," by Colonel Cleaveland).

Dr. Lodge says that the term hundredweight bears marks of confusion on its surface, and had better be avoided; what does he say to this use of hundredweight weights, not intended to mean pull of gravity?

This Warrant is dated four years before the first edition of the "Principia," in which the downward tendency of a weight was first clearly demonstrated as due to the attraction of the Earth, although mere surmises had been propounded by early astronomers, and in "Troilus and Cressida" we have—"As the very centre of the earth, drawing all things to it."

But Acts of Parliament on "Weights and Measures" were extant hundreds of years before the first appearance of the "Principia"; and when the standard pound weight was defined in these Acts, it was the lump of metal preserved at the Exchequer that was described, and not the pressure on the bottom of the box in which it was kept.

13. Formerly, the words *vis inertiæ*, or *inertia*, were used instead of the modern word *mass* (often used in ordinary language as the equivalent of *bulk*). But it is useful to notice that inertia is not always the same thing as weight or mass, or even proportional to them.

Thus the inertia of a body is increased by the presence of the surrounding medium; the inertia of a sphere moving in a frictionless incompressible liquid is increased by half the weight of the liquid displaced, and of a cylinder moving perpendicular to the axis by the weight displaced; while an elongated projectile requires rotation about an axis for stability of flight, in consequence of its inertia being different for different directions of motion.

The inertia of a pendulum, or of the train in § 2, is increased to an appreciable extent by the presence of the surrounding air.

Again, the inertia of a rolling hoop is twice its weight, of a cylinder is half again as great, of a billiard ball is 40 per cent. greater; and the inertia of a bicycle, or of the train we have considered in § 2, when the *rotary inertia* of the wheels is taken into account, must be increased by a fraction of the weight of the wheels and axles equal to k^2/a^2, where a is the radius of a pair of wheels, and k the radius of gyration of the wheels and axle about the axis of rotation.

For the same reason the centre of inertia does not always coincide with the centre of gravity, or centre of mass. The buffers of a railway carriage should be at the height of the centre of inertia; and this is easily seen to be at a height

$$h\Big/\left(1+\frac{w}{W}\frac{k^2}{a^2}\right)$$

above the axles, w denoting the weight of the wheels, W of the body of the carriage, and h the height of its centre of gravity above the axles.

The recommendations of the A.I.G.T., in their "Syllabus of Elementary Dynamics," will only serve to widen the increasing gulf between theoretical treatises and the Applied Mechanics which engineers use, unless the Committee of the A.I.G.T. will set to work to invent a totally new word, such as *heft*, to express the pull of gravity on a given weight, as an equivalent of the French word *pesanteur;* it is hopeless to attempt todegrade the, old word *weight* into the subsidiary secondary meaning so long as in commerce, and in the Acts of Parliament, *weight* invariably means quantity of matter, *copia materiæ*.

A. G. Greenhill.

APHANAPTERYX AND OTHER REMAINS IN THE CHATHAM ISLANDS.

In a former letter I sent you some account of the finding of the *Aphanapteryx* in the Chatham Islands. I have now gone more carefully over the bones I collected there, and some additional notes may not be without interest. I find that, of the heads I have obtained, a number are much larger than that of *Aphanapteryx broeckei* (Schlegel), and are therefore rightly assigned, I think, to a distinct species. The tarso-metatarsus, as figured by M. Milne-Edwards, however, may, I think, prove to belong not to *Aphanapteryx*, or at any rate not to a species with so robust a tibia. I found several tarso-metatarsi in near relation to the tibiæ and femora, and heads of *A. hawkinsi*, and they are all without exception much shorter and stouter bones in proportion to the tibiæ and femora. Out of the same strata which contained *Aphanapteryx*, I obtained a number of the bones of the skeleton of a *Fulica* very nearly related to *F. newtoni*. Like the *Aphanapteryx* bones, they vary very much in size, some being equal, others much larger than those of *F. newtoni*. So much so that I am inclined to recognize them as different species, or at least different races. The larger species I have named *F. chathamensis*. The portions I have had before me are the pelvis, the femur, the tibia, and metatarsus. I have portions of a large ralline skull, which may be that of this *Fulica*, but it is rather too imperfect to enable me to speak more confidently at present. The tarso-metatarsi of this bird agree much more closely with the tarso-metatarsus assigned in M. Milne-Edwards's plate to *Aphanapteryx*. Of the *Aphanapteryx* I possess the complete cranium, femur, tibia, metatarsus, humerus, and pelvis. Among the other interesting specimens so far identified, are the humeri and pelvis of a species of Crow half as large again as *C. cornix*. They agree closely with those of a true *Corvus*. I have designated it as *Corvus moriorum*, as I found some of these bones among the remains scattered round a very ancient Moriori cooking-place, which had become uncovered by the wind in the strata in which *Aphanapteryx* occurs. Indeed, in this kitchen-midden I gathered portions of the *Aphanapteryx*, of a large swan, of several species of ducks, and of a *Carpophaga* indistinguishable from the species now living on the islands—a species (*Carpophaga chathamica* mihi[1]) new to science. I may say that it is easily distinguished from *C. novæ-zealandiæ* by the breast-shield in both sexes being altogether duller than, and not extending so far ventrally as, in the latter. The head, neck, and breast are of the same colour—a dull green, with purple and green metallic reflections when viewed with the bird between the light and the eye. It is, however, most markedly distinguished by the pale lavender colour of the external border of the wings, the much paler colour of the lower back and rump, and by the black on the under surface of the tail feathers being prominent on all the rectrices except on the anterior portions of the outer tail feather on each side, and passing under the tail coverts in a broad wedge. Mr. Travers relates that he was informed by one of the early settlers on Pitt Island that he remembered the first appearance of the pigeon in the islands. This statement cannot well be accepted in face of the presence of the bird's bones in a midden so ancient as that I have referred to above. In the *Aphanapteryx* beds, I obtained also the portions of a skull of a species of *Columbidæ*, apparently of a *Columba*, of which I can say little till I am in possession of more material. I have obtained also bones of the small hawk (*Harpa*), showing that it existed on the islands, whereas it is now unknown there, although *Circus gouldi* is not uncommon.

At about 3 feet below the floor of a small cave, which the weathering limestone has deposited, I obtained portions of a pigmy Weka (*Ocydromus pygmæus*), and also the limb bones of a rat. If they have been gradually covered to this depth by the fall of particles from the roof, as there seems no reason to doubt, their age must be very great; but whether that would take us back to a date antecedent to the arrival of the Morioris in the Chatham Islands is a more difficult question to answer with our present data.

So far, the birds of whose presence in the Chatham Islands till now we have had no knowlege, are: *Harpa ? ferox*, *Nestor meridionalis* and *? N. notabilis*, *Corvus*

---

[1] ? *Carpophaga chathamensis* of Rothschild, P.Z.S. 1891, p. 312, pl. xxviii. —Ed.]

moriorum, *Ocydromus pygmæus*, *Fulica newtoni*, *F. chathamensis*, *Aphanapteryx hawkinsi*, *Ap.*? spp., *Chenopis sumnerensis*, *Carpophaga chathamica*, *Columba* sp.

HENRY O. FORBES.

Canterbury Museum, April 2.

ADMIRAL MOUCHEZ.

WE have already referred to the loss which French science has recently sustained in the sudden death of the director of the Paris Observatory, at the age of 71. It falls to the lot of few sailors in any country to take so large a share in scientific progress as did Admiral Mouchez, or to combine great administrative capacity with thorough knowledge and power of initiation.

His love for astronomy and geodesy first made itself felt when he was at the Collège Louis le Grand. Appointed to the navy in 1843, he was captain of a frigate in 1861, but three years before this he had communicated to the Academy of Sciences observations of the partial eclipse of the sun seen by him at Buenos Ayres on September 7, 1858. He was then in that locality constructing the hydrographical map of the eastern coast of South America. A year or two later he presented to the Academy a map of Paraguay, and he was presented as a candidate for filling the seat vacated by the untimely death of Bravais in 1863. But he was outvoted, and he continued his hydrographical work. He published a description of the coast of Brazil, and he observed an annular eclipse of the sun (on October 30, 1864) at San Catharina, Brazil.

When in 1872 expeditions were being organized by all countries to observe the transit of Venus in 1874, Mouchez was placed in command of the party which was destined for the island of Saint Paul. The climatic conditions of this island—either the winds are very violent, or the heaven is nearly always overcast—did not seem to favour the observers. The head of the expedition had the greatest difficulty in reaching his post, and it was in the middle of a violent storm that he had to approach the large volcano which was to be his station.

The evening of the day before the transit the rain fell in torrents; but the next day, at the moment wished for, by quite a fortunate chance, the storm cleared in consequence of a change of wind, and the veil of mist which covered the sky suddenly vanished; the observation was thus made under most favourable conditions. Mouchez was able to recognize the atmosphere of Venus very distinct from that of the Sun at the moment of contact.

The astronomical expedition which he commanded was composed of naturalists as well as astronomers; it has furnished science with interesting accounts of the geology, zoology, and botany of the islands of St. Paul and Amsterdam its neighbour.

On Mouchez's return to France he was promoted Commander of the Legion of Honour at the same time that he was nominated a member of the Academy of Sciences in the place of the astronomer Mathieu. In October 1875, at the annual public séance of the five academies, he gave an account of his expedition to the island St. Paul.

In 1878 he obtained from the French Admiralty the funds required for establishing at Montsouris, with the same instruments used by him at St. Paul, a school of astronomy for the use of marine officers and masters. This school is in full prosperity, and every year about a dozen men are trained in conducting astronomical and magnetical observations.

When Le Verrier died, on September 13, 1877, Mouchez, then commander, was appointed to the directorship of the National Observatory, and nearly simultaneously with this Commander Mouchez received the rank of Rear Admiral. He was put on the Reserve List in 1880.

Admiral Mouchez showed himself, at the Observatory, an active administrator. He brought about many marked improvements in the different branches of the establishment. He suggested the establishment of a practical school of astronomy, which has been worked for eight years consecutively, and has furnished all the French observatories with a remarkable supply of young astronomers. Thirty have passed through the two years' course.

Admiral Mouchez always encouraged useful researches, and the magnificent work undertaken with so much success by the brothers Henry in celestial photography, and the development of the *equatorial coudé*, under the fostering care of M. Loewy, must be specially mentioned here.

But by far the most important result of this kind which we owe to the Admiral's clear foresight and power of dealing with men is to be found in the Chart of the Heavens, which will remain as one of the memorable works of the science of the nineteenth century. It was on the proposal of the director of the observatory that the Academy of Sciences convoked foreign astronomers to take part in the Congress which, on three different occasions, assembled with so much success at the Paris Observatory.

This vast undertaking would have been impossible without the genius of the French nation and without such a man as Mouchez. It is essentially an international work which England should have started, but alas! in such matters our science is scarcely national; it is parochial, and so it must remain until the relations between science and the Government are changed.

Admiral Mouchez was a very zealous promoter of colonial observatories. He travelled to Algiers in order to preside over the inauguration of the large establishment erected by M. Trépied. This very year, having travelled to Tunis to recruit his failing health, he had taken steps for creating an astronomical station in the town of Zaghouan, and he was advocating the building of observatories at Tahiti and Tananarivo at the time of his death.

There are few astronomers who will not feel the death of Admiral Mouchez as the loss of a dear friend, and one in whom loyalty, honesty, and simplicity of character were so blended that the great services rendered by the savant were almost forgotten in the esteem felt for the man.

NOTES.

M. HECKEL, the President of the Botanical Section of the French Association for the Advancement of Science, proposes, as special subjects for discussion at the approaching meeting of the Association, to be held at Pau, the flora of the Alps and of the Pyrenees, and a comparison between them; and the best means of arranging and preserving botanical collections.

PROF. T. H. HUXLEY has been elected President, and Sir Henry Roscoe and the Master of University College, Oxford, two of the Vice-Presidents, of the Association for Promoting a Teaching University for London. Motions on the whole favourable to the plans of the Association have been carried by the Senate of the University of London and the Council of University College.

PROF. RAMSAY, in his report as Dean of the Faculty of Science in University College, London, has to record many changes during the past session. Reference is, of course, made to the retirement of Prof. Croom Robertson from the Chair of Philosophy, and to the appointment of Dr. James Sully as his successor. Prof. Ramsay's predecessor as Dean, Prof. Lankester, expressed to him his regret that he had not taken steps to ascertain the number of original investigations carried out during the time of his Deanship; and it occurred to Prof. Ramsay that no more fitting task could devolve on the Dean than to chronicle how far the progress of science is due to those, students and teachers, who work in University College. His colleagues have responded to his inquiries, and he has thus been able to lay before the Council a list of publications amounting in all to 84 separate memoirs or books. They contain accounts of researches in which professors, assistants, students, former students who are still at work in the College have taken part; and Prof. Ramsay maintains that in this, as well as in the routine of teaching, the College fulfils the duties of a true University. The record, he contends, equals, if it does not surpass, that of any University in the kingdom.

SINCE Saturday last Mount Etna has been in a state of eruption, and many severe shocks of earthquake have been felt in the surrounding country. From midnight till six o'clock on Saturday evening there were eleven distinct shocks. About noon on Saturday a great fissure opened on the summit of the mountain, from which lava began to issue with great rapidity. During the following night the eruption assumed alarming proportions, and huge quantities of lava streamed down the sides of the mountain. This rapidly flowed in two streams—one going in the direction of Nicolosi and the other towards Belpasso. There was a severe earthquake shock in the immediate vicinity of the volcano on Saturday night. On Sunday the people of Nicolosi assembled for mass outside the cathedral, and remained kneeling in the open air, being afraid to enter owing to the continued shocks of earthquake. At five o'clock in the evening the shocks continued, and very loud subterranean rumblings were heard, giving the impression of a terrible storm. Twelve houses and a portion of a church were destroyed. The eruption continued very active. On Monday it was stated that the rumblings had grown less frequent, and there were indications that the eruptions from the newly-formed fissure were about to cease. The principal crater, however, showed signs of renewed activity. On Tuesday the following telegram was despatched from Catania through Reuter's agency:—"The eruption of Mount Etna is again rapidly increasing in volume and intensity. Five craters at different points on the mountain are showing great activity. Loud explosions occur continually, and this morning there was a strong shock of earthquake. Giarre, on the coast to the north of Catania, has been reduced to ruins, and the whole country round has suffered severely. A number of engineers who have been sent to the points immediately threatened express fears that the wells will blow up on contact with the lava. There is no panic, and in the circumstances the people maintain a fairly calm demeanour."

A TERRIBLE disaster has happened in the neighbourhood of the sulphur springs of St. Gervais, a little way off the road from Geneva to Chamonix. According to a Reuter's telegram, despatched from Bonneville, Haute Savoie, on July 12, the calamity was due to the fact that the lower end of the glacier of Bionnay became detached from Mont Blanc and fell into the torrent beneath. It carried away with it the little village of the same name. The masses of ice and the wreck of the village formed a dam which held up the waters for some time, until they suddenly broke through the obstruction and burst like a cataract into the mountain stream, known as the Bon Nant, which flows by St. Gervais les Bains. These thermal springs, the medicinal virtues of which attract many visitors to the hotel during the year, rise in the wooded ravine of Montjoie, through which the Bon Nant or "Good Stream" passes on its way down to meet the river Arve. The gorge in which the Etablissement des Bains, erected at an altitude of 2066 feet above the level of the sea, stands, or rather stood, is narrow, and the hotel consisted of five separate buildings joined together by walls of stone roughly hewn from the mountain side. At a quarter past two on Tuesday morning or thereabouts, the people in the hotel were awakened by a terrific noise of rushing water, and the crashing of rocks one against the other. Then a furious gust of wind drove through the gorge. The next moment a torrent of water, carrying with it fragments of rock, trees, and débris of all descriptions, hurled itself upon the hotel. Of the five buildings, three were utterly destroyed, another was nearly so, while the fifth remained almost unhurt, owing its safety to its position, which was high above the course of the Bon Nant. Passing down the valley, the torrent struck the village of Le Fayet, which was almost entirely demolished. The wreckage of the houses was swept down the stream for miles into the river Arve, on the surface of which corpses and débris of all kinds were seen floating all day on Tuesday. According to the latest calculations on Tuesday evening, there were no fewer than 200 victims, more than half of whom were staying at the bathing establishment of St. Gervais.

THE following are among the Civil List pensions granted during the year ended June 20:—to Mrs. Caroline Emma Carpenter, £100, in consideration of the services rendered by her late husband, Dr. Philip Herbert Carpenter, F.R.S., to science, and of the sad circumstances in which she was left by his death; to Mr. Thomas Woodhouse Levin, £50, in consideration of the services he has rendered to education and philosophy and mental science, of his blindness, and of his inadequate means of support; to Dr. George Gore, F.R.S., £150, in consideration of his services to chemical and physical science; to Mr. Henry Dunning Macleod, M.A., £100, in consideration of his labours as a writer upon economical subjects; to Mr. Henry Bradley, £150, in consideration of his labours in connection with the "New English Dictionary"; to Miss Letitia Marian Cole, £30, Miss Henrietta Lindsay Cole, £30, and Miss Rose Owen Cole, £30, in recognition of the services rendered by the late Sir Henry Cole to the cause of artistic and scientific education; and to Mrs. Jeanie Gwynne Bettany, £50, in consideration of the services rendered to the spread of scientific knowledge by the numerous writings of her husband, the late Mr. G. T. Bettany, M.A.

MR. THOMAS HANBURY has presented to the Botanical Institute at Genoa the very rich collection of vascular plants made by the late Prof. Willkomm, of Prague. It comprises as many as 14,472 species, the greater number being European or from the adjacent districts of Asia and Africa. It is especially rich in plants of the Spanish Peninsula, and includes most of Willkomm's original type-specimens.

THE Society of Natural History of St. Petersburg has despatched Dr. K. N. Denkenbach on a mission to explore the flora of the Black Sea.

THE death is announced of Prof. Giovanni Flechia, Vice-President of the Reale Accademia delle Scienze of Turin.

THE series of fifteen water-colour paintings of the volcanic district in New Zealand, which were lent by Miss Constance F. Gordon Cumming to the Indian and Colonial Exhibition, are now lent to "The Castle" at Nottingham, where they will be shown for some little time. They were in the Indian and Colonial Exhibition at the time of the great eruption of Mount Tarawera, which destroyed the beautiful Terraces.

THE weather during the past week has been changeable, with frequent rain, more particularly in the north and west; 1·7 inch was measured on the west coast of Ireland on the morning of the 12th instant. At the time of our last issue a deep depression lay over the north of Scotland, the barometer being below 29 inches, while a moderate westerly gale was blowing in the

Channel, with a high sea; and other depressions have subsequently travelled to the northward of our islands. The weather, however, remained fair, but cloudy, in the southern parts of the kingdom, and fog prevailed on the north-east coast on Monday. The distribution of barometrical pressure has, for the most part, been favourable to westerly winds, the high barometer being situated over the north of France. A change, however, set in on Monday, accompanied by strong easterly winds and a falling barometer, the highest readings having shifted northward, with their centre situated to the eastward of our islands. These conditions were followed by fresh disturbances, accompanied by rainy and unsettled weather. Temperature has been lower than of late, although but little below the average; the highest day readings have seldom reached 70°. The *Weekly Weather Report* issued on the 9th showed that, for that week, bright sunshine continued fairly prevalent over the eastern and southern districts, and that there was a considerable excess of rainfall in Ireland and the northern and western parts of Scotland.

THE United States Weather Bureau has just published Bulletin No. 1, containing some interesting notes on the climate and meteorology of Death Valley, California. This valley lies between lats. 35° 40′ and 36° 35′ N. and longs. 116° 15′ and 117° 5′ W., and owes its name to the fate of a party of immigrants, who, about 1850, perished from thirst. The principal feature of interest about the place is that, although situated about 200 miles from the sea, it is said to lie 100 feet or more below the sea level, as determined from barometrical observations. The observations now published were commenced by the Geological Survey and the Signal Service, and were continued by the Weather Bureau during five months from May to September, 1891, and we believe these are the only regular observations, with trustworthy instruments, that have been made there. The principal meteorological features are the excessive heat and dryness; the temperature rises occasionally to 122° in the shade, and rarely falls during the hot season below 70°. It is said that the thermometer has sometimes reached 130°, and once even 137°. The diurnal range of the barometer is characteristic of the form found in continental valleys, being of the purest single maximum type, and has the largest amplitude known. The rainfall was extremely light, and was always either a slight sprinkle or a thunderstorm. The total fall for the five months was only 1·4 inches. It showed a distinct diurnal frequency; nearly all the hours of rain being during the night. Sand storms were also observed on several occasions.

THE Deutsche Seewarte has just issued Part IV. of their meteorological observations made at distant stations. The observations are made three times daily, and monthly means are added in the form agreed upon for international meteorological publications. These observations are especially valuable both on account of the remoteness of the places and of the details which are given about the stations and the instruments used. This volume contains observations made (1) at six stations in Labrador for 1887; (2) at Walfisch Bay for 1889; (3) in the Cameroon estuary, from April 1889 to June 1890; (4) at Bismarckburg, Togoland, West Africa, from June 1889 to May 1890; (5) at Chemulpo, Korea, from July 1888 to December 1889; (6) at Mohammera, mouth of the Euphrates, from June to August 1885; and (7) at Bushire, from September 1885 to March 1886. In some cases the introductory text contains general remarks relating to the tides and prominent features of the climate.

IN February 1888, Dr. E. Etienne was sent to Banana by the Congo Free State to direct the sanitary service, and he made regular meteorological observations there, six times daily from December 1, 1889, to May 16, 1891, which have now been published by the State. The range of temperature during the year 1890 presented great regularity, the absolute maximum, 93°·6, occurred in March, and the minimum, 61°·9, in July; the lowest maximum was 73°·9 in July, and the highest minimum, 79°·2, in April. The greatest monthly variability (the difference of the monthly mean from one month to another) was 5°·0 between May and June. The winds are very uniform: a land breeze from south-east to south at sunrise, then calm till about 11h. a.m.; a sea-breeze from south-west till about 7h. p.m., and a second calm about 10h. p.m. The rainy season of 1889–90 numbered fifty days, with a mean daily fall of 0·49 inch. The most remarkable fall was 1·2 inch in 45 minutes. The rainy season of 1890–91 differed considerably from the former; the number of wet days was only 29, with a mean daily fall of 0·52 inch, the total amount being about five-eighths of that in the previous year. In addition to the above there is a very small amount of rain in the dry season.

THAT iron is always present in small quantities in chlorophyll has been asserted over and over again in botanical text-books. Dr. H. Molisch, who has recently investigated the subject of the presence of iron in plants, disputes this, and asserts that he has never found a trace of iron in the ash of chlorophyll. He states that iron occurs in plants in two forms—in that of ordinary iron-salts, and in the "masked" condition, in which it is so closely combined with organic substances that the ordinary reagents fail to detect it. In this form iron occurs both in the cell-wall and in the cell-contents, but it does not enter into living protoplasm.

IN one of the alcoves of the Museum of the Academy of Natural Sciences, Philadelphia, there are various fossil bones of extinct animals belonging to the Pleistocene period, and along with them a human bone. These "finds" were presented to the Academy in 1846 by Dr. Dickeson, who discovered them in a single deposit at the foot of the bluff in the vicinity of Natchez, Mississippi. Specimens—one from the human bone, the other from one of the bones of a Mylodon—have been submitted for analysis to Prof. F. W. Clarke, chemist of the U.S. Geological Survey; and the result is reported by Dr. Thomas Wilson, of the Smithsonian Institution, in the current number of the *American Naturalist*. The human bone is in a higher state of fossilization than the Mylodon. It has less lime and more silica. In their other chemical constituents they are without any great difference. Of lime the bone of the Mylodon has 30·48 per cent., while that of man has but 25·88 per cent. Of silica the Mylodon has 3·71 per cent., while man has 22·59 per cent. Dr. Wilson refers to the ordinary uncertainty of this test when applied to specimens from different localities and subjected to different conditions, but points out that in the present case no such differences exist. The bones were all encased in the same stratum of blue clay, and were subjected practically to the same conditions and surroundings.

MR. A. J. COOK, of the Agricultural College, Michigan, has been making experiments to determine how much honey is needed to enable bees to secrete one pound of wax, and he has found that the amount is eleven pounds of honey. This is less than the amount given by Huber, and more than that stated by Viallon and Hasty. An account of the experiments and of many other interesting facts relating to apiculture will be found in a report included in Bulletin 26 of the U.S. Department of Agriculture.

AN interesting memoir of John Hancock, with portrait, opens the latest instalment (vol. xi. Part 1) of the Natural History Transactions of Northumberland, Durham, and Newcastle-upon-Tyne. The writer, Dr. Embleton, gives an excellent account of Hancock's masterly power of mounting animals. He notes also Hancock's remarkably intimate knowledge of the characters and habits of birds. "He could describe and imitate their motions and sounds so vividly, by feature, voice, and posture, as to be most instructive and at the same time amusing, whilst he convinced his auditors of the naturalness of his pantomime."

A paper on the Tertiary Rhynchophora of North America, by Mr. Samuel H. Scudder, has been reprinted from the Proceedings of the Boston Society of Natural History (Vol. 25). The assortment of the mass of Tertiary insects from American western deposits, upon which Mr. Scudder has been engaged for many years, has brought to light an unexpectedly large number of Rhynchophora, about eight hundred and fifty specimens having passed through Mr. Scudder's hands; of these, however, fully a hundred have proved too imperfect for present use or until other specimens in better condition may show what they are. Seven hundred and fifty-three specimens have served as the basis of a Monograph now being printed. More than half (431) of these specimens come from the single locality of Florissant, Colo., and excepting a single specimen from Fossil, Wyo., and another from Scarboro', Ontario, the others are divided between three localities not widely removed: the crest of the Roan Mountains in western Colorado, the buttes on either side of the lower White River near the Colorado-Utah boundary, and the immediate vicinity of Green River City, Wyoming. One hundred and ninety-three species are determined, divided among ninety-five genera, thirty-six tribes or sub-families, and six families, by which it will be seen at once that the fauna is a very varied one. It is richer than that of Europe, where there have been described (or merely indicated) only one hundred and fifty species, of which nine come from the Pleistocene. The older Tertiary rocks of America, therefore, are found to have already yielded nearly twenty-eight per cent. more forms than the corresponding European rocks. Although it is evident to any student of fossil insects that even in Tertiary deposits we possess but a mere fragment of the vast host which must have been entombed in the rocks, Mr. Scudder contends that we have already discovered such a variety and abundance of forms as to make it clear that there has been but little important change in the insect fauna of the world since the beginning of the Tertiary epoch.

In a paper on artesian water in New South Wales, printed in the current number of the Journal and Proceedings of the Royal Society of that colony, Prof. Edgeworth David says that water rises to the surface in many parts of the east-central portions of Australia from mud or mound springs. These occur chiefly in strata of Cretaceous age. The most remarkable groups are perhaps those on the Lower Flinders, which have been described by Mr. E. Palmer in the Proceedings of the Royal Society of Queensland. The springs erupt thin mud and hot water intermittently, and thus gradually build up around their orifices mounds of mud of a rudely crateriform shape. At Mount Browne, on the Lower Flinders, several feet above the general level of the plain, is a mud spring mound covered with gigantic tea-trees (*Melaleuca leucodendron*), among the matted roots of which the hot water steams in clear shining crystal pools. At the top of the mound is a large basin of hot water, stated to be fathomless. The roots and branches of the tea-trees lying in this water become coated with a soft green vegetable substance, with air bubbles clinging to them. Innumerable small bubbles of carbon-dioxide are continually rising to the surface of the basin. The water is too hot for the hand to bear for any length of time, but when cooled it is good for use and always bright and clear, and free from any taste, while that in the adjoining cold springs is extremely disagreeable. The temperature of the water in two of these hot springs at Mount Browne is 120° F. No change has been observed in the hot springs as regards level or temperature since 1865, when a cattle station was settled there.

Among the curiosities in the mines and mining building at the Chicago Exhibition will be a solid gold brick, weighing 500 pounds, and worth 150,000 dollars. It will be exhibited by a mine owner at Helena, Mon.

Dr. C. F. MacDonald, who has been present at the seven executions by electricity in New York State, has submitted to the State authorities a report, in which he contends that experience has thoroughly justified the abolition of hanging. When the new method is used, death, he maintains, occurs before any sensation of pain or shock can be conveyed to the brain of the condemned. Dr. MacDonald's conclusions are endorsed by a hundred physicians who have acted as witnesses at different executions.

The raisin industry is being gradually developed in Victoria, and promises shortly to be sufficient to supply the requirements of the colony. So says Mr. J. Knight, who writes on the subject in the new Bulletin of the Victoria Department of Agriculture. Extensive planting, he says, is going on in various parts of the colony, from the extreme west at Mildura along to the east as far as Wangaratta, the largest plantation being in the well-known Goulburn Valley. In this locality not only has the manufacture of raisins received attention during the last six years, but the products of the currant vine also are now being placed on the market.

The second volume of the *Photographic Annual* has been issued. It includes a vast number of advertisements, but contains also some able articles, among which we may especially note Mr. Albert Taylor's general view of the progress of astronomical photography during 1891.

In 1891 wide-spread alarm was caused in America by the presence of several species of destructive locusts in different parts of the country, particularly in the Western States. A general summary of these incursions was given in Mr. C. V. Riley's annual report for 1891, and now a Bulletin has been issued by the U S. Department of Agriculture giving the detailed reports of the agents who carefully examined the invaded districts.

A catalogue of the marine shells of Australia and Tasmania, compiled by John Brazier, F.L.S., is being printed by order of the trustees of the Australian Museum, Sydney. The first part, dealing with Cephalopoda, has been issued. The task cannot be accomplished very quickly, as it entails the examination of many thousands of specimens, both dry and in spirits. The catalogue will include not only the species represented in the general Museum collection, but also those in the Hargreave's collection presented to the trustees by the late Mr. Thomas Walker, and those recently purchased from Mr. Brazier.

Mr. R. Etheridge, Jun., gives, in the latest instalment of the Transactions of the Royal Society of Victoria, an interesting account of a fine specimen of an unusually large species of the genus Belonostomus, obtained in 1889 by Mr. George Sweet, of Brunswick, Melbourne, in the Rolling Downs formation (Cretaceous) of Central Queensland. The fossil exhibits a long, slender fish, with deep, narrow ganoid scales and feeble fins, bent upon itself at about the middle point, and wanting the greater part of the head. Species that are apparently allied have been recorded from the Upper Cretaceous of Western Europe, India, and Brazil, and Mr. Etheridge notes that the present discovery is of great interest as extending still further the ascertained geographical range of the genus during Cretaceous times.

The very extensive alterations in botanical nomenclature proposed in Kuntze's "Revisio Generum" has prompted a proposal, emanating from the four eminent German botanists, Ascherson, Engler, Schumann, and Urban, with the assent of a number of their colleagues, for a revision of De Candolle's "Lois de Nomenclature Botanique." The essential points of the propositions are that the starting-point for the priority of genera, as well as of species, shall be the year 1753, the date of the publication of Linnæus's "Species Plantarum"; that "nomina nuda" and "semi-nuda," *i.e.* names without a diagnosis, or with only a very imperfect diagnosis, shall be rejected, as well as figures without a diagnosis; that no generic name shall be rejected because of its similarity to another generic name, even if it differ only in the last syllable, but that, if the difference be in spelling only, the later name must be rejected; that the names of certain large and universally known genera be retained, even though they would have to be rejected by the strict rules of priority. English botanists are invited to signify their assent or otherwise to these propositions.

At the meeting of the Linnean Society of New South Wales, on May 25, Mr. Pedley exhibited a very fine and perfect saw, about 5 feet long, of the saw-fish *Pristis zysron*, Bleeker. The fish, without the saw, was about 19 feet long, and was captured in a net at Evans River, N.S.W. The number of pairs of rostral teeth for this species is usually given as from 26–32; the specimen exhibited had only 25 pairs, all in place. At the same meeting, Mr. Hedley exhibited, on behalf of Mr. Rainbow, a spider of the family *Epëiridæ*. This rare and remarkable insect furnishes an addition to the fauna of Australia, and it is supposed that a new genus may be required for its reception.

Mr. W. A. Rogers, writing to *Science* from Colby University, Waterville, Me., confirms testimony given by Mr. Kunz as to the fact that the hardness of diamonds is not perceptibly reduced by cutting and polishing. In the earlier years of Mr. Rogers's experience in ruling upon glass he was accustomed to select a gem with a smoothly-glazed surface, and, the stone being split in a cleavage plane inclined at a rather sharp angle to the natural face selected, this split face was ground and polished. In this way he was able to obtain at several points short knife-edges, which gave superb results in ruling. It was soon found, however, that after ruling several thousand rather heavy lines the diamond was liable to lose its sharp cutting-edge, and this experience became so frequent that he was compelled to resort to the method now employed, that of grinding and polishing both faces to a knife-edge. He has one ruling diamond prepared in this way, which has been in constant use for four years, and its capacity for good work has not yet been reduced in the slightest degree. A diamond prepared by Mr. Max Levy, of Philadelphia, has given even better results, and so far it shows no evidence of wear.

The *Bulletin de la Société des Naturalistes de Moscou* (1891, Nos. 2 and 3) contains a very interesting paper, in French, by Prof. A. Pavloff and Mr. G. W. Lamplugh, on the Speeton clays and their equivalents. These clays, which have long occupied the attention of geologists, have acquired of late a new interest owing to close resemblance between their fauna and that of similar deposits in other countries, even as far distant as Russia. The work consists of three parts: the first part, devoted to the description of the Speeton clays and their Lincolnshire equivalents, has been written by Mr. Lamplugh, and will, no doubt, be published in English as well. The second part, by Prof. Pavloff, is devoted to the description of the Cephalopods found in these clays, the Speeton forms being compared with those of other countries, and especially those of Russia. A table giving the succession of the subdivisions of the Jurassic and Cretaceous deposits, with their leading fossils, in the two Russian localities where they are best represented (Moscow and the lower Volga), is given by the author, and it differs from a previous table by the introduction of a new series, named Petchorian, which, although it has the thickness of but a few inches, has nevertheless a very peculiar fauna, of a well-determined character. However, for the present it is not possible to classify it either under the Jurassic or the Cretaceous formation. The table is followed by a detailed description of twenty-five species of Belemnites, of which eight are new, the chief interest of this description being in the attempt to give in each case the genealogical relations of closely allied species, and in a special chapter devoted to the geological history of Belemnites generally and the descent of various species supposed to have originated from the *Belemnites tripartitus* of the middle Jurassic and Lias epoch. In a subsequent paper, which will contain the third part of the work—namely, a comparison of the Speeton clays with those of other localities—the author proposes to describe in the same way the Speeton Ammonites, which are even more interesting than the Belemnites; and he hopes to be able then to give a more positive answer as to where the separation must be taken between the Jurassic and the Cretaceous deposits of the Speeton clays and analogous deposits.

Mr. Matthias Dunn writes to us from Mevagissey, Cornwall, that the fishing-boat *Mispah* landed a large shark there lately which had got entangled in her mackerel nets. Its length was 11 feet 2 inches, and in its stomach were two considerable-sized congers. The creature proved to be Couch's Ponbeagle Shark, or *Lamna cornubica* of Cuvier.

The additions to the Zoological Society's Gardens during the past week include a Tiger (*Felis tigris* ♂ jr.) from Amoy, China, presented by Mr. Robert Bruce; two Mountain Ka-kas (*Nestor notabilis*) from New Zealand, presented by the Earl of Onslow, K.C.M.G.; a Chilian Sea Eagle (*Geranoaetus melanoleucus*) from Chili, presented by Mr. Edward Jewell; a Broad-fronted Crocodile (*Crocodilus frontatus*) from West Africa, presented by Mr. G. T. Carter; a Common Boa (*Boa constrictor*) from South America, presented by Mr. A. E. Oakes; a Macaque Monkey (*Macacus cynomolgus* ♀) from India; a Kinkajou (*Cercoleptes caudivolvulus*) from Demerara, deposited; a Hippopotamus (*Hippopotamus amphibius* ♂) bred in Antwerp; sixteen Common Boas (*Boa constrictor*) from South America, purchased; an Indian Muntjac (*Cervulus muntjac* ♂) born in the Gardens.

OUR ASTRONOMICAL COLUMN.

Lunar Photography.—Dr. L. Weinek, of the Prague Observatory, has been the recipient of several photographs of the moon from Prof. Holden for the purpose of making enlargements from them. The photographs were obtained with the large equatorial of the Observatory at Mount Hamilton, and an illustration of one of the enlargements is given in *L'Astronomie* for July. The photograph is of the large crater Petavius, 153 kilometres in length. With M. Weinek's apparatus the photograph was enlarged twenty times, giving a lunar image of nearly three metres in diameter. At first sight the photograph looks as if the enlargement had been carried a little too far, but when held at arm's length the effect is very fine. The most striking features noticeable are the narrow river-like lines, which are numerous and very alike in appearance. Whether these are really photographic or not of course we cannot say, as we have not seen the original negatives, but they seem to be rather too distinct and natural to be taken for any impression other than photographic. What these rivers, if we may use such a term, are composed of is at present a subject of mere conjecture, but the day is not far off when a very careful systematic study will have to be undertaken to settle some of the questions that have been recently raised in respect to our satellite's surface.

COMET SWIFT (1892 MARCH 6).—The ephemeris of this comet for the ensuing week, taken from the *Edinburgh Circular*, No. 28, is as follows :—

Berlin Midnight.

1892.	R.A.	Decl.	log Δ.	log r.	Br.
	h. m. s.	° ′			
July 14	0 58 26	+49 20·8			
15	59 6	49 31·4			
16	0 59 44	49 41·8	0·2459	0·2776	0·15
17	1 0 19	49 51·9			
18	0 52	50 1·8			
19	1 22	50 11·5			
20	1 49	50 21·0	0·2488	0·2884	0·14

Brightness at time of discovery taken as unity. The comet lies in the southern extremity of the constellation of Cassiopeia.

OPPOSITION OF MARS.—All observatories which have the necessary equipment are especially invited by the United States Naval Observatory to join with them in making observations of the coming opposition of Mars. Observations should commence on June 20 to September 23, this period being divided into three parts, the comparison stars for the first section being O.A.S. 20970, η Capricorni, 27 Capricorni, φ Caoricorni, Lacaille 8851, 41 Capricorni, D.M. – 20°, 6923, Lalande 42700. It may be mentioned that observations made in accordance with the special circular which the U.S. Observatory has issued will be reduced by them.

SUN-SPOTS.—*Himmel und Erde* for July contains two very good photographs of the sun at the time of the great spot in the month of February. They were photographed by Dr. Lohse, at the Astrophysical Observatory at Potsdam. One was taken on February 13 at 10h., and shows the large group near central transit with a smaller group on the limb ; while in the other, the large group is nearer the western limb. A small disc represents the relative size of the earth for comparison.

REMARKABLE PROMINENCES.—The sun's atmosphere this year has been subject to many violent disturbances, indicated to us by the presence of spots, prominences, &c. The spots, with special reference to the February group, have already received much attention, but not so with the prominences. From a set of forty observations of the latter made between March 1 and May 31, 1892, by M. Trouvelot, 23 of these, as he says, belonged to the most interesting type, *i.e.*, eruptive. On April 6, 1892, there appeared an arched like prominence on the sun's limb, extending through 12°, the length of its base being 144,932 and its height 92,664 kilometres ; to give an idea of the size of this arch, it may be stated that as many as 22 globes the size of our earth might have simultaneously passed under it. At 10h. 54m., on the 8th of the same month, a huge column of light, in shape rather like a candle flame, rose to a height of 115,830, extending, in a little over half-an-hour, to 169,884 kilometres. A prominence of far greater length, occupying 34° of the solar limb, but of much less height than those mentioned above, was visible on April 15. Its base covered 410,632 kilometres, thus exceeding ten times the circumference of our earth.

GEOGRAPHICAL NOTES.

AT the last meeting of the Council of the Royal Geographical Society for the present session, it was unanimously agreed to admit women as Fellows on the same terms as men. There is nothing in the society's charter to limit the membership to men, and the proposal of admitting ladies has been made several times, and on the last occasion—two years ago—was nearly carried. As there will not be another meeting of the society until the opening of next session, the election of the first lady F.R.G.S. cannot take place until November.

THE Annual Congress of the French Geographical Societies meets this year at Lille in the first week of August, for the consideration of questions relating mainly to France and its colonies. The French Association for the Advancement of Science will hold its meeting at Pau, as we have already announced, in the third week of September. Its Geographical Section will be presided over by M. E. Anthoine, head of the French Map Department and of Graphic Statistics under the Minister of the Interior. In all departments of geography there is a remarkable revival of interest among Frenchmen at the present time, although the narrow or national aspect of the subject predominates over the wider or cosmopolitan.

A CURIOUS account of the piratical Tugere tribe of New Guinea has been published in most of the continental geographical journals on the authority of "an English medical missionary, Dr. Montague," who was picked up by a Dutch war-vessel near the boundary of Dutch and British New Guinea. This gentleman told a remarkable narrative of his capture and imprisonment by the Tugere, but as no English missionary of his name is known to be in New Guinea, nor has any mission station been recently raided by the Tugere, there is no doubt that some mistake has been made. It is impossible that so serious an incident as the imprisonment of an English missionary could be unknown in this country, and unless strong evidence were forthcoming, it is difficult to believe that such a thoroughly piratical people as the Tugere could show the diligence in agriculture and the relatively high civilization with which the story credits them.

M. E. A. MARTEL continues his researches into the subterranean geography of France. In March last he descended the "unfathomable" Creux-Percé on the plateau of Langres, proving it to be only 180 feet deep. It is a hollow in Jurassic limestone, and, although open to daylight, forms a natural ice-house, having a temperature of 28°F. when the external air was at 58°. In June he examined the still more remarkable Creux de Souci in the department of the Puy de Dôme. It proved to be a rounded cavity in recent basalt, 115 feet deep, having the appearance of being formed by a great gas bubble. A stagnant pool occupied the bottom of the pit, and above it the air was so much impregnated with carbonic acid that a candle would not burn. In this instance also the temperature fell as the distance from the surface increased, that of the external air being 51°, of the air at the bottom of the shaft 34°, and the water itself 34°·3. The Paris Society of Commercial Geography recently awarded a medal to M. Martel on account of the practical value of his researches in leading to the regulation of the underground drainage of Greece.

EASTER ISLAND.

THE prehistoric remains of Easter Island make it for archæologists one of the most interesting islands in the Pacific. They will therefore read with interest an elaborate paper in the Report of the U.S. National Museum for 1888–89, which has just been issued. The paper is entitled "Te Pito Te Henua, or Easter Island," and is by William J. Thomson, Paymaster, U.S. Navy. It records the results of researches made by Mr. Thomson during a visit paid to Easter Island by the American vessel, the *Mohican*, towards the end of 1886. The *Mohican* anchored in the Bay of Hanga Roa on the morning of December 18, 1886, and remained till the evening of the last day of the year, when she sailed for Valparaiso. Mr. Thomson and some of his comrades, interested in the relics of a past phase of life in the island, made the most of the short time at their disposal, and his essay will certainly rank among the most important contributions which have been made to our knowledge of the subject with which it deals.

He begins with a general account of Easter Island, and in this part of his work has succeeded in presenting compactly and clearly much valuable information. Of the geological features of the island he says that they are "replete with interest." The formation is purely volcanic, and embraces every variety pertaining to that structure. The tufaceous lavas form the most prominent element in the physiognomy of the island. To them, with the action of the trade-winds and heavy rains, is due the fact that Easter Island is surrounded by precipitous cliffs, rising in some cases to a thousand feet in height. The formation is extremely friable, and by the action of the elements enormous masses are continually disappearing beneath the waves that beat on the unprotected shore. Both on the coast-line and in the interior there are many natural caves. Some of these are of undoubted antiquity, and bear evidence of having been used by early inhabitants as dwellings and burial-places. It is reported that small images, inscribed tablets, and other objects of interest have been hidden away in such caves and lost through land-slides.

The climate is not unlike that of Madeira, with one wet and one dry season. Yams, potatoes, and taro are cultivated, the young plants being protected from the fierce heat of the sun by a mulching of dried grass gathered from the uncultivated ground. Bananas are grown, and so is sugar-cane, but the natives do not extract the juice for the purpose of making sugar. A wild gourd is common, and constituted the only water-jar and domestic utensil known to the islanders. Mr. Thomson saw no flowering plants indigenous to the soil, but ferns of many varieties are common, and grow in profusion in the craters of the volcanoes. Except in a few exposed places, the slopes of the hills and the valleys are covered with a perennial grass resembling the Jamaica grass (*Paspalum*). This natural growth supplies ample pasturage for cattle and sheep.

The only quadrupeds peculiar to the island are several varieties of rodents. Fish abounds in the surrounding sea, and has always been the principal means of support for the islanders. Turtles are also plentiful, and are highly esteemed. The turtle occupies a prominent place in tradition, and is frequently represented in the hieroglyphics. It appears also on sculptured rocks.

According to the traditions of the natives, the island was discovered by King Hotu-Matua, who came from the land in the direction of the rising sun, with two large double canoes and three hundred chosen followers. Mr. Thomson thinks there may have been more than one migration of people to the island, and that their traditions may have been mingled together; but there can, he believes, be no reasonable doubt about the progenitors of the present islanders being of the Malayo-Polynesian stock. The people were shockingly treated by some of the early voyagers, and in 1863 the majority of the able-bodied men were kidnapped by Peruvians, who carried them away to work in the guano deposits of the Chincha Islands and the plantations in Peru. Just before the arrival of the *Mohican* a complete census of the population had been taken by Mr. Salmon, who found that the total number of natives was 155. The children are not much darker than Europeans, but the skin assumes a brown hue as they grow up and are exposed to the sun and trade-winds. The eyes are dark brown, bright, and full, with black brows and lashes not very heavy. The countenance is usually open, modest, and pleasing. In disposition the natives are cheerful and contented. They all profess Christianity, but there are now no missionaries among them, and they display a tendency to return to the old Pagan ideas. Tattooing is no longer practised, but every islander advanced in life is ornamented in all parts of the body.

At one time the island must have been densely populated, and the surviving monuments show that the inhabitants had attained to a higher civilization than that of other Polynesians. The ancient stone houses at Orongo were thoroughly explored by Mr. Thomson and his party. These curious dwellings seem to have been built for the accommodation of the natives while the festival of the "sea-birds' eggs" was being celebrated. During the winter months the island is visited by great numbers of sea-birds, most of which build their nests among the ledges and cliffs of the inaccessible rocks. Some, however, choose two islets lying a few hundred yards from the south-west point of Easter Island, and the natives are believed to have selected Orongo as a convenient spot for watching for the coming of the birds. The fortunate person who obtained possession of the first egg, and returned with it unbroken to the expectant crowd, became entitled to certain privileges and rights during the following year. Near Orongo are the most important sculptured rocks in the island. They are covered with carvings intended to represent human faces, birds, fishes, and mythical animals, all very much defaced by the time and the elements. The most common figure is a mythical animal, half human in form, with bowed back and long claw-like legs and arms. According to the natives, this symbol represented "Meke-Meke," the great Spirit of the sea.

On the high bluff west of Kotatake Mountain the party discovered the ruins of a settlement extending more than a mile along the coast-line and inland to the base of the hill. These remains bear unmistakable evidences of being the oldest habitations on the island. The houses are elliptical in shape, with doorways facing the sea, and were built of uncut stone. Some of the walls are standing, but the majority are scattered about in confusion. Each dwelling was provided with a small cave or niche at the rear end, built of loose lava stones, which was in a number of instances covered by an arch supported by a fairly shaped key-stone. The recesses were "undoubtedly designed to contain the household gods."

Mr. Thomson has, of course, much to say about the stone images with the idea of which Easter Island is intimately associated in the minds of all who have devoted any attention to its antiquities. Every image in the island was counted, and the list shows a total of 555 images. Mr. Thomson says:—

"Of this number forty are standing inside of the crater, and nearly as many more on the outside of Rana Roraka, at the foot of the slope where they were placed as finished and ready for removal to the different platforms for which they were designed; some finished statues lie scattered over the plains as though they were being dragged toward a particular locality but were suddenly abandoned. The large majority of the images, however, are lying near platforms all around the coast, all more or less mutilated, and some reduced to a mere shapeless fragment. Not one stands in its original position upon a platform. The largest image is in one of the workshops in an unfinished state, and measures 70 feet in length; the smallest was found in one of the caves, and is a little short of three feet in length. One of the largest images that has been in position lies near the platform which it ornamented, near Ovahe; it is 32 feet long, and weighs 50 tons.

"Images representing females were found. One at Anakena is called 'Viri-viri Moai-a-Taka,' and is apparently as perfect as the day it was finished; another, on the plain west of Rana Roraka is called 'Moai Putu,' and is in a fair state of preservation. The natives have names for every one of the images. The designation of images and platforms as obtained from the guides during the exploration was afterwards checked off in company with other individuals without confusion in the record. The course gray trachytic lava of which the images were made is found only in the vicinity of Rana Roraka, and was selected because the conglomerate character of the material made it easily worked with the rude stone implements that constituted the only tools possessed by the natives. The disintegration of the material when exposed to the action of the elements is about equivalent to that of sandstone under similar conditions, and admits of an estimate in regard to the probable age. The traditions in regard to the images are numerous, but relate principally to impossible occurrences, such as being endowed with power to walk about in the darkness, assisting certain clans by subtle means in contests, and delivering oracular judgments. The legends state that a son of King Mahuta Ariiki, named Tro Kaiho, designed the first image, but it is difficult to arrive at an estimation of the period. The journals of the early navigators throw but little light upon the subject. The workshops must have been in operation at the time of Captain Cook's visit, but unfortunately his exploration of the island was not directed towards the crater of Rana Roraka.

"Although the images range in size from the colossus of 70 feet down to the pigmy of 3 feet, they are clearly all of the same type and general characteristics. The head is long, the eyes close under the heavy brows, the nose long, low-bridged, and expanded at the nostrils, the upper lip short and the lips pouting. The aspect is slightly upwards, and the expression is firm and profoundly solemn. Careful investigation failed to detect the slightest evidence that the sockets had ever been fitted with artificial eyes, made of bone and obsidian, such as are placed in the wooden images.

"The head was in all cases cut flat on top, to accommodate the red tufa crowns with which they were ornamented, but the images standing outside of the crater had flatter heads and bodies than those found around the coast. The images represent the human body only from the head to the hips, where it is cut squarely off to afford a good polygon of support when standing. The artists seem to have exhausted their talents in executing the features, very little work being done below the shoulders, and the arms being merely cut in low relief. The ears are only rectangular projections, but the lobes are represented longer in the older statues than in those of more recent date.

"The images were designed as effigies of distinguished persons, and intended as monuments to perpetuate their memory. They were never regarded as idols, and were not venerated or worshipped in any manner. The natives had their tutelary genii, gods, and goddesses, but they were represented by small wooden or stone idols, which bore no relation to the images that ornamented the burial platforms. The image-makers were a privileged class, and the profession descended from father to son.

Some of the natives still claim a descent from the image-makers, and refer to their ancestors with as much pride as to the royal family.

"The work of carving the image into shape, and detaching it from the rock of which it was a part, did not consume a great deal of time, but the chief difficulty was, in the absence of mechanical contrivances, to launch it safely down the slope of the mountain and transport it to a distant point. It was lowered to the plain by a system of chocks and wedges, and the rest was a dead drag accomplished by main strength. A roadway was constructed, over which the images were dragged by means of ropes made of indigenous hemp, and sea-weed and grass made excellent lubricants. The platforms were all built with sloping terraces in the rear, and up this incline a temporary road-way was constructed of a suitable height, upon which the statue could be rolled until the base was over its proper resting-place. The earth was then dug away to allow the image to settle down into position, the ropes being used to steady it in the meantime."

Interesting as these monuments are, they are less remarkable than the incised tablets which show that the Easter Islanders had worked out for themselves a kind of writing. The following account of the tablets is given by Mr. Thomson. Their existence "was not known until the missionaries settled upon the island, Numerous specimens were found in the possession of the natives, but no especial attention appears to have been directed towards them. Several persons, belonging to vessels that were wrecked at Easter Island, report having seen such tablets, but the natives could not be induced to part with them. The three hundred islanders who emigrated to Tahiti had in their possession a number of tablets; they created some attention on account of the remarkable skill with which the figures were executed, but they were highly prized by the owners, and no effort was made to secure them because their real value was not discovered. The Chilian corvette *O'Higgins* visited Easter Island in January 1870, and Captain Gana secured three tablets, two of which are on deposit in the National Museum at Santiago de Chili, and the third was sent to France, but does not appear to have reached its destination. Paper impressions and casts were taken from the Chilian tablets for the various Museums of Europe. Those sent to the English Ethnological Society created some interest after a time, but others sent to Berlin were regarded as stamps for marking native cloth (*Mittheilungen*, July 1871). Seven of these tablets are now in the possession of Tepano Jansser, Bishop of Axieri, all in excellent state of preservation.

"While the *Mohican* was at Tahiti, the Bishop kindly permitted us to examine these tablets and take photographs of them. These tablets were obtained from the missionaries who had been stationed on Easter Island, and they ranged in size from 5½ inches in length by 4 inches broad, to 5½ feet in length and 7 inches wide. Diligent search was made for specimens of these tablets during our visit to Easter Island. At first the natives denied having any, but Mr. Salmon knew of the existence of two, and these were finally purchased after a great deal of trouble and at considerable expense. The tablets obtained are in a fair state of preservation. The large one is a piece of driftwood that from its peculiar shape is supposed to have been used as a portion of a canoe. The other is made of the toromiro wood indigenous to the island. In explanation of the disappearance of these tablets, the natives stated that the missionaries had ordered all that could be found to be burned, with a view to destroying the ancient records, and getting rid of everything that would have a tendency to attach them to their heathenism, and prevent their thorough conversion to Christianity. The loss to the science of philology by this destruction of valuable relics is too great to be estimated. The native traditions in regard to the incised tablets simply assert that Hotu-Matua, the first king, possessed the knowledge of this written language, and brought with him to the island sixty-seven tablets containing allegories, traditions, genealogical tables, and proverbs relating to the land from which he had migrated. A knowledge of the written characters was confined to the royal family, the chiefs of the six districts into which the island was divided, sons of those chiefs, and certain priests or teachers, but the people were assembled at Anekena Bay once each year to hear all of the tablets read. The feast of the tablets was regarded as their most important *fête* day, and not even war was allowed to interfere with it.

"The combination of circumstances that caused the sudden arrest of image-making, and resulted in the abandonment of all such work on the island, never to be again revived, may have had its effect upon the art of writing. The tablets that have been found in the best stage of preservation would correspond very nearly with the age of the unfinished images in the workshops. The ability to read the characters may have continued until 1864, when the Peruvian slavers captured a large number of the inhabitants, and among those kidnapped were all of the officials and persons in authority. After this outrage, the traditions, &c., embraced by the tablets, seem to have been repeated on particular occasions, but the value of the characters was not understood, and was lost to the natives.

"A casual glance at the Easter Island tablets is sufficient to note the fact that they differ materially from other kyriologic writings. The pictorial symbols are engraved in regular lines on depressed channels, separated by slight ridges intended to protect the hieroglyphics from injury by rubbing. In some cases the characters are smaller, and the tablets contain a greater number of lines, but in all cases the hieroglyphics are incised, and cover both sides as well as the bevelled edges and hollows of the board upon which they are engraved. The symbols on each line are alternately reversed; those on the first stand upright, and those on the next line are upside down, and so on by regular alternation.

"This unique plan makes it necessary for the reader to turn the tablet and change its position at the end of every line; by this means the characters will be found to follow in regular procession. The reading should commence at the lower left-hand corner, on the particular side that will bring the figures erect, and followed as the characters face in the procession, turning the tablet at the end of each line, as indicated. Arriving at the top of the first face, the reading is continued over the edge to the nearest line, at the top of the other side, and the descent continues in the same manner until the end is reached. The Boustrophedon method is supposed to have been adopted in order to avoid the possibility of missing a line of hieroglyphics."

A man called Ure Vaeiko, one of the patriarchs of the island, professed to have been under instructions in the art of hieroglyphic reading at the time of the Peruvian visit, and claimed to understand most of the characters. The photographs of the tablets owned by the Bishop were submitted to this old man, who related with fluency and without hesitation the legend which he declared to be appropriate to each. "The story of all the tablets of which we had knowledge," says Mr. Thomson, "was finally obtained, the words of the native being written down by Mr. Salmon as they were uttered, and afterwards translated into English."

Ure Vaeiko's tales, with the translations, are printed in Mr. Thomson's paper; and, as they are manifestly not the reciter's own invention, they have a certain interest for students of anthropology. But whether they represent the meaning of the inscriptions on the mysterious tablets is another question. It is noteworthy that, although Ure Vaeiko's fluent interpretation of the tablets was not interrupted, "it became evident that he was not actually reading the characters." "It was noticed that the shifting of the position did not accord with the number of the symbols on the lines, and afterwards, when the photograph of another tablet was substituted, the same story was continued without the change being discovered." These facts raise a doubt as to the trustworthiness of his pretensions to knowledge. However, Mr. Thomson does not seem to have yet presented a full account of the work accomplished in connection with this curious problem. "Results of an extremely interesting nature," he says, "are barely outlined at present, and not in shape to be presented herewith. It is not considered expedient to attempt an explanation of the symbols until the subject can be treated exhaustively."

It remains for us only to say that the paper is richly illustrated, and accompanied by a map of Easter Island.

EMBRYOGENY OF GNETUM.

THE remarkable observations of Treub on the mode of fertilization in the *Casuarinaceæ*,[1] have been followed by some almost equally interesting, by Herr Karsten, on the formation of the embryo in *Gnetum*. The following is a summary of the more important points, as described in the *Botanische Zeitung*.

The inner integument of the ovule develops into a long tube leading to the apex of the nucellus, and projecting far beyond the other two integuments; it forms, at its apex, a drop of sweet fluid which captures the pollen-grains carried by the wind or possibly by insects. The outermost very thick integument becomes fleshy and bright-coloured, and is attractive to herbivorous animals. In the division of the cells of the nucellus at an early stage there is no evident predestination of one, as there is in most Angiosperms, as the mother-cell of the embryo-sac. In *Gnetum Gnemon* and *neglectum* there are usually two, three, or even more embryo-sacs which appear equally capable of further development; while in *G. edule*, and allied forms, the author found only one. In the division of the contents of the embryo-sac no differentiation of a female apparatus takes place in any of the species examined; no corpuscles or special ovum-cells are formed, and no antipodals; but the protoplasm of the embryo-sac divides into a parietal layer of primordial cells, which appear to be altogether equivalent, and which represent so many ovum-cells capable of fertilization.

---

[1] See NATURE, vol. xlv. p. 548.

As the pollen-tube lengthens, its nucleus gives off a smaller vegetative nucleus, probably soon after the entrance of the tube into the tissue of the nucellus. The two nuclei remain very near one another; the vegetative nucleus or prothallium cell remains unchanged, while the generative nucleus increases greatly in size and divides into two. In *G. edule* the apex of the pollen-tube has now entered the apex of the embryo-sac; while in *G. neglectum* it appears to make a curve to avoid the apex of the sac, and becomes closely applied to its lower portion. After the pollen-tube has entered the embryo-sac its vegetative nucleus disappears, while each of the two generative nuclei surrounds itself with a membrane of protoplasm, and the nucleus of each of these generative cells divides into four or eight. The actual coalescence of the male and female nuclei was not observed; but a number of small nuclei were detected in the male generative cells, in addition to its four (or eight) comparatively large male nuclei, which the author regards as the nuclei of the primordial ovum-cells which have wandered into the male generative cells; and the coalescence must take place within the male generative cell. After the entrance of the pollen-tube, the parietal layer of protoplasm of the embryo-sac, in which the female primordial cells are imbedded, breaks up into an endosperm tissue.

The author regards *Gnetum* as representing a higher type of the order *Gnetaceæ* than the other genera, *Welwitschia* and *Ephedra;* the fact that no endosperm is formed before fertilization indicating an advance on other Gymnosperms. The presence of a large number of embryo-sacs, and the absence in them of antipodals, may indicate some analogy with *Casuarina*. The processes described above finally negative, in the opinion of the author, the theory that the antipodals are a survival of the female prothallium of Vascular Cryptogams; they appear, rather, to be a degenerate and functionless female sexual apparatus. According to this view, there are, in the embryo-sac of Angiosperms, two female sexual apparatuses of similar origin, the vegetative nuclei of which coalesce in each; but one of the two apparatuses is altogether abortive. Both the antipodals and the egg-apparatus or embryonic vesicles consist of an archegone reduced to a single cell.

A. W. B.

INTERNATIONAL CONGRESS OF EXPERIMENTAL PSYCHOLOGY.

THE second session of the above Congress will be held in London on Monday, August 1, 1892, and the three following days, under the presidency of Prof. H. Sidgwick. The Congress will assemble in the rooms of University College, Gower Street (kindly lent for the purpose), from 10 to 1 and from 2 to 4.30. The following papers have been arranged for:—

Dr. ALEXANDER BAIN ...	"The Respective Spheres and the Mutual Aids of Introspection and Experiment in Psychology."
Prof. M. BALDWIN ...	"Suggestion and Will."
Prof. BEAUNIS	"Psychological Questioning" (Des questionnaires psychologiques).
Dr. BÉRILLON	"The Applications of Hypnotic Suggestion to Education."
Prof. BERNHEIM	"The Psychical Character of Hysterical Amblyopia."
M. BINET	"The Psychology of Insects."
Prof. DELBŒUF	"The Appreciation of Time by Somnambulists."
Dr. DONALDSON	"Laura Bridgman."
Dr. VAN EEDEN... ...	"Principles of Psycho-Therapeutics."
Prof. EBBINGHAUS ...	"Theory of Colour-perception."
Dr. GOLDSCHEIDER ...	"Investigations into the Muscular Sense of the Blind."
Prof. STANLEY-HALL ...	"Recent Researches in the Psychology of the Skin."
Prof. HENSCHEN... ...	"The Visual Centre in the Cortex of the Calcarine Fissure."
Prof. HEYMANS	"Inhibition of Presentations."
Prof. V. HORSLEY ...	"The Degree of Localization of Movements and Correlative Sensations."
Prof. PIERRE JANET ...	"Loss of Volitional Power (l'aboulie)."
Prof. N. LANGE	"A Law of Perception."
Prof. LIÉGEOIS	"The Female Poisoner of Aïn-Fezza."
Prof. LEHMANN	"Experimental Inquiry into the relation of Respiration to Attention."
Dr. LIGHTNER-WITMER	"The Direct and Associative Factors in Judgments of Æsthetic Proportion."
Prof. LOMBROSO	"The Sensibility of Women, Normal, Insane, and Criminal."
Dr. MENDELSSOHN ...	"Investigations into the Parallel Law of Fechner."
Prof. LLOYD MORGAN ...	"The Limits of Animal Intelligence."
Prof. G. E. MÜLLER ...	"The Experimental Investigation of Memory."
Prof. MÜNSTERBERG ...	"The Psycho-Physical Basis of the Feelings."
Mr. F. W. H. MYERS ...	"The Experimental Induction of Hallucinations."
Dr. W. R. NEWBOLD ...	"The Characteristics and Conditions of the Simplest Forms of Belief."
Prof. PREYER	"The Origin of Numbers."
Prof. RIBOT	"General Ideas."
Prof. RICHET	"The Future of Psychology."
Prof. SCHÄFER	"The Anatomical and Physiological Relations of the Frontal Lobes."
Mrs. SIDGWICK	"Experiments in Thought-Transference."
Dr. E. B. TITCHENER ...	"Binocular After-images."
Prof. TSCHISCH	"Relation of Reaction-time to the Breadth of Perception."
Dr. VERRIEST	"The Physiological Basis of Rhythmic Speech."
Dr. WALLER	"On the Functional Attributes of the Cerebral Cortex."

The Meetings of the Congress will be General and Sectional. It is provisionally arranged that the General Meetings will be held on Monday or Thursday, and on the afternoons of Tuesday and Wednesday; and that the Sectional Meetings will be held on Tuesday and Wednesday Mornings, and if necessary on Thursday Morning. There will be two Sections at least: Section A, Neurology and Psychophysics; and Section B, Hypnotism and Cognate Questions. Under Section A will fall, for example, the papers of M. Binet, Profs. Henschen, Horsley, Schäfer, Waller, &c.; under Section B will fall the papers of Dr. Bérillon, Profs. Bernheim, Delbœuf, Liégecis, Dr. Van Eeden, Mr. F. W. H. Myers, and Mrs. Sidgwick.

Reports will be given in by Profs. Sidgwick and James and M. Marillier of the results of the census of hallucinations which it was decided to carry out at the first Session of the Congress (Paris, 1889).

A Committee of Reception has been formed, which includes, among others, the following names:—Dr. A. Bain, Dr. D. Ferrier, Mr. F. Galton, Dr. Shadworth Hodgson, Prof. V. Horsley, Dr. Hughlings Jackson, Dr. Charles Mercier, Prof. Croom Robertson, Dr. G. J. Romanes, Mr. Herbert Spencer, Mr. G. F. Stout, Dr. J. Ward, and Dr. de Watteville.

The fee for attendance at the Congress is ten shillings, which will entitle to a printed report of the proceedings. Any intending members who have not yet paid the fee are requested to send it to Prof. Sully.

During the Congress letters may be addressed to Members at the Council Room, University College, Gower Street, London, W.C., where each Member is requested to inscribe his name, on his first attendance at the Congress.

F. W. H. MYERS,
Leckhampton House, Cambridge.
JAMES SULLY,
East Heath Road, Hampstead, London, N.W.

SCIENTIFIC SERIALS.

THE current number of the *Royal Agricultural Society's Journal* is, perhaps, of more than usual interest. The first article is on Vermin of the Farm, by J. E. Harting, and is followed by an editorial note on the same subject. The plague of "mice" on the hill pastures of Scotland this spring gives a special interest to these articles. It appears that the Scotch plague is caused not by mice, but by fieldvoles (*Arvicola agrestis*), and the destruction they have wrought in the hill pastures of Scotland arises from the fondness of these voles for the delicate white stems of the hillside herbage. Judging from the reports of similar plagues in previous years it would appear that the natural enemies of the vole—the short-eared owl and the kestrel hawk—are far more efficacious remedies than any artificial means yet devised for the destruction of the voles; hence a paper on Wild Birds in relation to Agriculture, by Earl Cathcart, is very opportune, protesting as it does against the careless destruction of such birds as the owl, the hawk, and the rook. The Journal also contains a second paper by Mr. Dan Pidgeon on the Evolution of Agricultural Implements. A suggestive paper by Mr. William E. Bear on Desirable Agricultural Experiments advocates extensive experiments to test the economy of nitrogenous manuring by means of leguminous crops. Other papers in this number are Contagious Footrot in Sheep, by Prof. G. T. Brown; Variations of the Four-course System, by Gilbert Murray; and the Trial of Ploughs at Warwick, by F. S. Courtenay.

SOCIETIES AND ACADEMIES.

Oxford University Junior Scientific Club, May 27.—The biennial conversazione of the Club was held in the University Museum, when an address inaugural to the recently founded "Robert Boyle lectures of the O.U.J.S.C." was delivered by Prof. Sir Henry W. Acland, Bart., K.C.B., F.R.S., on Robert Boyle, his life, work, and influence on science. A very interesting series of exhibits was shown by the various departments of the Museum and by the University Observatory, illustrating recent progress in their particular branches of science. Of special interest were the exhibits by the Rev. F. J. Smith on shadow and objective spark photography, illustrated by pictures of objects in rapid motion; by Mr. Cecil Carus-Wilson, of natural and artificial musical sands; by the University Observers, of a series of splendid photographs illustrating recent improvements in astronomical and spectral photography; by the National Telephone Company, of telephonic apparatus; by Dr. Hunt, of preparations and cultivations illustrating the methods of isolation and identification of bacteria; by Mr. B. V. Darbishire, of a series of lantern views in the Caucasus and in the British East Africa Company's territory, the slides for which were kindly lent by the Royal Geographical Society. The Club is much indebted to the Royal Society, the Pharmaceutical Society, the Right Hon. the Earl of Cork and Orrery, Prof. Wyndham R. Dunstan, Prof. Odling, and other gentlemen for the loan of oil paintings, engravings, and relics of Robert Boyle and his contemporary men of science in Oxford.

June 3.—The President, Mr. W. Ramsden, in the chair.—The following papers were read:—The sub-salts of the alkali metals, by Mr. W. Pullinger.—The action of silicon-tetrachloride on benzene, by Mr. C. H. H. Walker.—Marriages of consanguinity, by Mr. H. Anglin Whitelocke.—A new and improved form of rotatory hypsometer, by Mr. S. A. Sworn (Balliol). Mr. C. J. Romanes was elected an honorary member of the Club.

June 14.—The President, Mr. W. Ramsden, in the chair.—The following papers were read:—The action of iodine on a mixture of sulphites and thiosulphates, by Mr. H. A. Colefax.—On marine nests, by Mr. W. B. Benham.

EDINBURGH.

Royal Society, June 20.—Dr. Traquair exhibited some remains of animals occurring in volcanic tuff at Teneriffe.—Dr. Hunter Stewart read a paper on the variations in the amount of carbonic acid gas in the ground air.—Dr. Buchan discussed the diurnal variations of barometric readings in the polar regions during summer. From observations made in the summer of 1876 and the two succeeding summers, in the central part of the North Atlantic, between 62° and 80° north latitude, he showed that only one maximum and one minimum occur during the day. Observations made by the *Challenger* staff in high antarctic latitudes during summer give the same result. A single maximum and a single minimum are also found in the interior parts of the polar continents, but these occur at different times of the day from the ocean maximum and minimum. Superposition of the two sets of variations gives a variation like that ordinarily observed.

July 4.—The Hon. Lord Maclaren, Vice-President, in the chair.—Dr. A. W. Hughes read a paper on the rotatory movements of the human vertebral column. Among other results he points out that while the lumbar vertebræ cannot rotate much about a vertical axis, the dorsal vertebræ are capable of considerable rotation—the total rotation of this part of the vertebral column being 45° or more—and the cervical vertebræ are still more free—the total amount being at least 90°.—Mr. R. Kidston discussed the genus *Lepidophloios*, Sternb.—Prof. C. G. Knott and Mr. A. Shand communicated some further notes on the volume effects of magnetization. Five iron tubes, with bores varying from 16·0 to 3·5 mm. diameter, but otherwise identical in form and substance, were subjected to a series of magnetizing forces. In low fields the thinner-walled tubes experienced the greater dilatations of internal volume; but in high fields the narrower bored tubes showed much the greater dilatations. For example, in field 1400 the dilatations of the tubes in order, beginning with the one of widest bore and thinnest wall, were $+4$, -3, -20, -53, and -129—each being multiplied by 10^{-7}. With the two tubes of widest bore, the change of volume had reached its limit at this high field, the substance being practically saturated; but with the tubes of narrowest bore there was no evidence of a limit being reached, the innermost layers of iron being evidently far from practical saturation. Some interesting illustrations of magnetic after-effect were also described.—Dr. A. B. Griffiths submitted a paper on the blood of the invertebrata.—Prof. Tait communicated the second part of a paper on the laws of motion. If we assume the principles of inertia of matter and conservation of energy (the energy of a self-contained system consisting of the kinetic energy of all its parts supposed to be moving with the speed of its centre of inertia, the kinetic energy of relative motion of its parts, and the potential energy of its parts), the fact that we cannot attach any definite meaning to the principle of conservation, except when the motion of the system is Galilei-wise, leads at once to the first and third laws of motion, since the centre of inertia moves uniformly in a straight line; and the second law becomes merely a definition of the word "force" as used in the first law, and as used instead of "action" and "reaction" in one interpretation of the third.

PARIS.

Academy of Sciences, July 4.—M. d'Abbadie in the chair.—On local disturbances produced underneath a heavy load uniformly distributed along a straight line normal to the two edges, on the upper surface of a rectangular beam: experimental verifications, by M. J. Boussinesq.—Resemblances in the march of evolution on the old continent and the new, by M. Albert Gaudry.—Experimental researches on falling bodies and the resistance of air to their motion: experiments performed at the Eiffel Tower, by MM. L. Cailletet and E. Colardeau. Metallic spheres were let fall from the second platform of the Eiffel

Tower, and their exact time of describing certain distances was measured to a hundredth of a second by means of an electric chronograph. The body was fixed to a very light thread wound round a set of inverted cones, each of which held 20m. of thread. The latter passed from one cone to another through two fine springs in contact, which contact was broken by the string pulling through, thus producing a mark on the chronograph. The retardation produced by the string was independently determined and found to be less than 0·001 per cent. The following laws were verified: that the resistance of the air is proportional to the area of the resisting surface; and that it is independent of the form of the surface. That it is also proportional to the square of the velocity was not found to be strictly true, since the resistance increased rather more rapidly. The amount of fall after which the velocity of the weights employed became uniform ranged from 60m. to 100m. Contribution to the study of the function of camphoric acid, by M. A. Haller.—A new contribution to the history of morbid associations; anthrax and paludism, by M. Verneuil.—Fixation of ammoniacal nitrogen on straw, by M. de Vogüé.—On the nature of the rotation of the knife-edge of a pendulum on its plane of suspension, by M. G. Defforges. This rotation is not a simple rolling, as was assumed by Euler and Laplace, but is compounded with a sliding motion, whose existence can be proved by means of interference fringes. The sliding is proportional to the amplitude and up to six or seven kgr. to the weight.—On the influence of the place of the external thermometer in observations of zenith distances, by M. Périgaud. In calculating the error due to refraction by Arago's method, the density of the layer of air in the neighbourhood of the objective is measured by a thermometer placed outside the room, near the north side of the observatory. It was sought to fulfil the conditions of the problem more rigidly by suspending a thermometer quite close to the objective. The zenith-distances, calculated on the basis of its indications, showed a difference of 0·2 to 0·8 from those obtained by Arago's method, which made the zenith distances too large. The writer's method has been adopted at the great transit-instrument of the Paris Observatory. —On the primary forms of linear differential equations of the second order, by M. Ludwig Schlesinger.—On the precise determination of the critical density, by M. E. Mathias. This determination is aided by the law of the rectilineal diameter, according to which in the curve of temperatures and densities the locus of the midpoints of the chords parallel to the axis of the ordinates is a straight line. This law, recently confirmed by Young's experiments, implies that the critical density is equal to the ordinate of the diameter which corresponds to the critical temperature. Calculated according to this law, the critical densities of methyl, ethyl, and propyl alcohol are found to be the same.—Influence of the mass of the liquid in the phenomena of heating, by W. A. Witz.—Measurement of the dielectric constant by electromagnetic oscillations, by M. A. Pérot. By the method described, the constant K was determined for glass, and found to range from 2·71 if charged for $72·6 \times 10^{-10}$ sec. to 5·727 if charged for $453·7 \times 10^{-10}$ sec.—On the composition of water and Gay-Lussac's law of volumes, by M. A. Leduc. The writer's researches on the densities of gases have led him to adopt the value 23·24 for the percentage of oxygen in the air. The density of oxygen was determined by a modification of Dumas's process, in which the hydrogen was absorbed by finely-laminated electrolytic copper. The atomic weight deduced was 15·88, while the mean of the best values for the density is 15·90. This shows that Gay-Lussac's law of volumes is only approximate.—On the nitrogen salts of platinum, by M. M. Vèzes.—Researches on the sodic pyrogallols, by M. de Forcrand.—On acetono-resorcine, by M. H. Causse.—Utilization of roasted iron pyrites for the manufacture of iron salts, by MM. A. and P. Buisine.—On the alterations of ferruginous waters, by M. F. Parmentier.—Reproduction of pure potassic nepheline, by M. André Duboin.—On the passage of dissolved substances through mineral filters and capillary tubes, by M. C. Chabrie.—On hæmocyanine, by M. Léon Frédéricq. —On the physiological determinism in the metamorphosis of the silk-worm, by M. E. Bataillon.—On a new *Temnocephala*, a parasite of *Astacoides madagascariensis*, by M. A. Vayssière. —Earthworms and tuberculosis, by MM. Lortet and Despeignes. Proving that worms can bring the bacillus to the surface, preserving all its virulent properties.—On the Californian disease, a disease of the vine caused by *Plasmodiophora californica*, by MM. P. Viala and C. Sauvageau.—An essay on vegetable statics, by M. Augustin Letellier.—On the cavern called the Creux de Souci (Puy-de-Dome), by MM. E. Martel, A. Delebecque, and G. Gaupillat.—On the lakes of the central plateau of France, by MM. A. Delebecque and E. Ritter.

BERLIN.

Physical Society, June 3.—Prof. Schwalbe, President, in the chair.—Dr. Gross continued his remarks on the subject of entropy.—Dr. Wien gave an account of experiments on the measurement of high temperatures, made in conjunction with Dr. Holborn, with a view to testing Le Chatelier's platinum and rhodium thermo-elements. They were first compared with an air-thermometer. The latter consisted of a glazed porcelain tube containing slightly rarefied air, the temperature being recorded by a manometer. The thermo-element was introduced into the cavity of the air-thermometer, and the readings of the respective instruments were compared between −80° and +1500°. Below 500° the thermo-element was not very sensitive, and is hence of use only for high temperatures. Alloys of platinum with 9, 10, 11, 20 and 40 per cent. of rhodium were tried. It was found that the E.M.F. increased with the increased percentage of rhodium, but that the most suitable alloy was that containing 10 per cent. of rhodium as recommended by Le Chatelier. The above experiments necessitated the determination of the co-efficient of linear expansion of Berlin porcelain. This was found to be ·000004. In some final experiments the melting-point of gold was determined to be 1073° and 1067°, of silver 972° and 968°, and of copper 1082°.

June 17.—Prof. Kundt, President, in the chair.—Prof. Vogel exhibited a remarkably fine series of coloured prints of oil paintings, &c., prepared in accordance with his method by Messrs. Vogel and Ulrich. The method consists in first taking a red, a yellow, and a blue negative of the object on plates specially sensitized for colours. The three negatives are then printed on to one and the same paper by means of complementarily coloured rollers or stones. In order to obtain the colours exactly complementary to those of the negatives, the colours used for printing were either the coloured sensitizers themselves or some substance whose equivalence to these had been determined spectroscopically. The application of the physical principles involved in the above yielded an approximate reproduction of the natural colours which was surprisingly complete, and will become more so as more and more coloured substances are discovered suitable as sensitizers.—Prof. Koenig described his new spectrophotometer. Its chief improvement consists in the introduction of Lummer and Brodhun's glass-cube, which is, however, so modified as to admit of the measurement of the relative intensities of the parallel rays falling into it.

Physiological Society, June 24.—Prof. du Bois Raymond, President, in the chair.—Prof. Kossel communicated the results of some experiments made by Dr. Monti on the absorption of oxygen by the tissues after death, using for this purpose their reducing action on photographic plates. The suprarenals, spleen, and thymus reduced most actively, while brain-substances produced but little effect. Dr. Lilienfeld had investigated the distribution of phosphorus in various tissues by means of micro-chemical reactions with ammonium molybdate and pyrogallol. The presence of phosphorus was usually strongly marked in the nuclei as compared with the cell-substance, except in the case of the cerebral ganglia, in which the reverse was frequently observed. Prof. Gad drew attention to a phenomenon, brought to his notice by Prof. Litten, which may be observed during normal human respiration, and consists in the downward passage of an obvious wave over the wall of the thorax at each inspiration and the upward passage of a similar wave at each expiration.

AMSTERDAM.

Royal Academy of Sciences, June 25.—Prof. van der Waals in the chair.—Prof. T. Forster spoke (1) On the action of heat upon tuberculous matter. According to former investigations by "pasteurizing" (*i.e.*, warming liquids to a temperature of 60 to 80° C. for a short time and cooling them immediately), bacteria of Asiatic cholera and typhoid-fever are killed at about

60°. From a hygienic point of view it is of still more importance to discover what is the lowest temperature at which the bacilli of tuberculosis are destroyed. It is established that tuberculosis is produced by the consumption of milk secreted by tuberculous cows. Meat also, coming from tuberculous cattle, sometimes contains infectious matter. By boiling heat, indeed, the bacilli of tuberculosis are killed. But if meat is prepared in the usual manner, even small pieces of it are not warmed thoroughly at 100° C.; milk, on the other hand changes in taste if boiled, so that most people do not like boiled milk. By a series of experiments, recently made, Prof. Forster has settled that the bacilli of tuberculosis are destroyed by a temperature of 60° C. acting during one hour, and by the action during six hours of a temperature of 55° C. Higher temperatures than 60°, for instance, 80, 90 or 95° C., destroy the infectious matter in milk from tuberculous cows, if they act during *ten* minutes; "pasteurizing," however, at 80° during *one* minute does not hurt the bacilli of tuberculosis. (2) On the development of bacteria at a temperature of melting ice. He had formerly demonstrated cultivations of bacteria, which produce light of phosphorescence. The same kind of bacteria are also able to develop and to multiply at a temperature of 0° C. He found that bacteria which have this peculiar quality, so interesting from a biological point of view, not only live in the sea, but are met with in brackish and fresh water, upon victuals, manures, etc., etc. This agrees with the fact that victuals, kept for some days in an ice-chamber, gradually assume a disagreeable smell and taste; and that meat can be preserved from putrefaction for days but not for weeks. If foods are to be preserved at a low temperature for a long time, beside cold a second agent is necessary—dryness. In the cooling rooms of the most modern establishments (slaughterhouses, stores, etc., etc.) no use is made of ice, which after melting moistens the atmosphere and the objects in the ice-chambers, but arrangements are made by which the atmosphere is cooled to a low temperature and at the same time kept perfectly dry.—M. Beyerinck spoke of the culture of organisms of nitrification on agar-agar and on gelatine. First it was stated, in accordance with the discovery of Warington and Winogradsky, that nitrification consists in two processess—the formation of nitrous acid from the ammonsalt by a specific bacterium and the oxidation of the nitrite into nitrate by another and independent species of bacterium. Secondly, that both these processes occur only when soluble organic matter is reduced to a minimum such as has been proved by the classic researches of Winogradsky and the Franklands. Even 0·1 per cent. of calcium-acetate retards nitrification strongly. Thirdly, it was found that organic matter in the solid state does not in the least interrupt or retard nitrification. Therefore an attempt was made—and successfully—to cultivate the nitrous and nitric bacteria on agar-agar, fully extracted with distilled water and afterwards boiled with the inorganic salts needed for nitrification. If with these salts some pure precipitated carbonate of lime was added to the agar it was possible to obtain a "chalk-agar-plate," whereon the nitrous bacteria of the soil, after their growth into colonies, could directly be numbered. For this purpose the chalk-agar is poured into a glass-box, and some soil suspended in sterilised water brought on the surface of the solidified plate. After three to four weeks the colonies become visible as the centres of clear, transparent, perfectly circular diffusion figures, formed by the solution of the carbonate of lime in the nitrous acid, the very soluble calcium-nitrite diffusing in all directions in the agar-plate. In this way it was found, for example, that out of c.a. 10 millogrammes soil taken from under a sod of white clover in a garden at Delft, thirty colonies of the nitrous bacterium could be cultivated. The species is the same as that described as the European form by Winogradsky, growing, as well as zooglœa, quite free, and possessing the form of a small, moveable mikrokok with one cilium. Gelatine, prepared with the same precautions as the agar, can also be used, but therein the production of nitrous acid soon ceases. The nitrous bacterium does not liquefy the gelatine. Though it does not grow or oxidize when organic matter is present, it does not lose these powers by this contact, as shown when brought anew under adequate conditions. The nitric bacterium was also isolated on fully extracted agar, to which 0·1 per cent. potassium-nitrite and some phosphate was added. The colonies are very small and coloured light yellow. They consist of very small non-moving mikrokoks or short ellipsoids. They lose their power of oxidizing nitrites by the contact of soluble organic matter, without thereby losing their power of growth. The nitric bacterium does not oxidize ammonsalts. It is also without action on potassium rhodanate and hydrochloric-hydroxylamine. It therefore does not seem to produce free acid such as the nitrous bacterium. A simple method for the formation of sterile plates of silica, with and without carbonate, was also described. Many preparations were demonstrated.

DR. MIVART'S ESSAYS.

Essays and Criticisms. By St. George Mivart, F.R.S. (London: Osgood, M'Ilvaine, and Co., 1892.)

DR. MIVART has collected in two portly volumes a number of essays and critical reviews which he has from time to time contributed to current monthly or quarterly literature. The ground covered is tolerably extensive; from "Jacobinism" and "The French Revolution" to "Weismann's Theories" and "Eimer on Growth and Inheritance;" from "Austrian Monasteries" and "The Greyfriars" to "Herbert Spencer" and "Hermann Lotze." We have read the whole, or almost the whole, with interest, and not without admiration of the author's wide knowledge, his earnest purpose, and his power of clear exposition. Here, however, we are chiefly concerned with those essays which deal with scientific problems. They are well worthy of reperusal in their present collected form, and that chiefly because Dr. Mivart holds definite and in some respects peculiar views on evolution, because he has the advantage of some training in philosophy, because he is a learned and acute critic, and because he has pre-eminently the courage of his convictions.

It is scarcely necessary to remind the readers of NATURE that Dr. Mivart is one of those who hold that natural selection has played a quite subordinate part in the evolution of organisms. He believes that the concurrence of certain external exciting causes acts in such a manner on internal predisposing tendencies as to determine by direct modification the evolution of new specific forms. Furthermore he affirms that, beyond the domains of merely physical science (which, though much, is not everything), reason demands a non-mechanical conception—namely, the conception of an immanent active principle or soul in everything which lives. And he contends that between the self-conscious reason of man and the mere sensuous feeling of the higher brutes, there is a great and impassable gulf fixed. These are among the more important positions which the author of these "Essays and Criticisms" assumes in the field of biological speculation. And to these may, perhaps, be added his condemnation of the doctrine of the relativity of knowledge, and his belief in common-sense realism, apparently on the assumption that the external reality of the objective world (as opposed to its *phenomenal* existence) is directly apprehended by the intellect, though it cannot be reached through sensuous feeling.

On all these matters Dr. Mivart has much that is interesting to say, and says it in an interesting manner. It would manifestly be impossible here to discuss so wide a range of problems. We therefore propose to select one matter—that of the relation of human reason to brute intelligence—on which to offer a few remarks.

In the essay entitled "A Limit to Evolution," the author seeks to establish the impossibility of mental evolution as applied to man. He insists, and rightly insists, that the great difference between man and the lower animals lies not in his bodily but in his mental constitution; and he contends, again in our opinion with perfect justice, that in order to examine this question we must begin by looking a little carefully into our own minds, and by examining our own acts and mental nature. As the result of this examination he finds that our psychical operations fall into two classes; on the one hand, there are feeling (sensitivity), imagination and sensuous memory, sensuous emotion, sense-perception, and sensuous inference; on the other hand, there are intellectual perception, ideation and conception, abstract ideas, and moral and æsthetic concepts. "The contrast, the difference of *kind*," he says, "which exists between this *intellectual conception* and the various forms of *feeling* is very great." We thus possess a dual psychical nature, on the one side sensuous, on the other side intellectual. The sense-perceptions of the one and the abstract ideas of the other "belong to utterly different categories, and a nature which has this power of abstraction is separated from any nature which has *not* that power, by a gulf which is an impassable *limit to evolution*, because feeling and intellect are both thus different in nature, and progress and develop along different and more or less diverging roads." But the psychical powers of brutes are limited to sense-perception, and give no evidence of the possession of the higher faculty of ideation and conception. Therefore the passage from the so-called mind of the brute to the conceptual mind of man is not only impossible but inconceivable.

Such in brief is Dr. Mivart's line of argument. Now, we hold that the distinction between the higher self-conscious, reflective, and conceptual powers of man, and his lower sensuous, non-reflective, and perceptual mental activities is a valid and valuable one, and one which is too often lost sight of. And we hold, further, that our author is right, in the main if not entirely, in denying to brutes the higher powers of conceptual thought. Again, we agree with Dr. Mivart in regarding the progress and development of sense-perception and abstract thought as more or less divergent. Where we part company with him is in the assumption, for such it appears to us, that these divergent lines of development cannot have a common origin. In all that he has written on the subject we fail to find any adequate justification for this dogmatic assertion so often and so confidently reiterated. The distinction between mere sense-perception and reflective thought is frequently drawn with admirable lucidity and clearness; but the impossibility of their having a common psychical root is merely asserted with a few rhetorical flourishes. We venture to question the assertion. Dr. Mivart is not, be it noted, content to assume the modest but perfectly legitimate scientific position that no one has yet succeeded in showing the early stages of the divergence, the tentative beginnings of the reflective process, the gradual focussing of the mental eye upon the processes of consciousness. He does not take his stand on a "not proven," but on a somewhat dogmatic "impossible"—not merely an "impossible" to this or that or the other factor in evolution from the nature of the factor, but broadly and generally an Impossible that is as worthy of a big initial letter as the Unknowable itself!

We cannot take leave of Dr. Mivart's volumes without again calling attention to the fact that they are full of matter interesting to the student of evolution. His scientific conclusions are not altogether those to which we have ourselves been led, though there are not a few matters on which we have the pleasure of agreeing with him; his psychological and philosophical views are not in all respects those which we have reached, though here again we are on many not unimportant questions on his side; but we believe him to be an honest and fearless inquirer after that Truth which stands on the title-page of a work to which, perhaps, for some of our readers, these volumes of essays may form a suitable introduction.

C. LL. M.

PHYSICAL OPTICS.

A Treatise on Physical Optics. By A. B. Basset, M.A., F.R.S. (Cambridge: Deighton, Bell, and Co., 1892.)

A NEW treatise on the higher branches of physical optics must be welcome to all who are interested in the subject. Mr. Basset explains in the preface the scope and aim of his book, and it is needless to say that he performs the task he has set himself with ability and success. If, nevertheless, we close the book with a feeling of disappointment, it is because we could have wished that the author had been more ambitious, and attempted to give us a little more than a compilation of the standard papers on the subject. There is one sentence in the preface which, though it evidently does not express what the author meant to say, yet may serve as a peg whereon to hang the only criticism which can fairly be raised against Mr. Basset's treatment of his subject. "I have a profound distrust," says the author, "of vague and obscure arguments based upon general reasoning instead of upon rigorous mathematical analysis." Now, if we are to have vague and obscure arguments, it does not seem to matter much whether they are founded upon general reasoning or upon mathematical analysis, however rigorous that may be. In a subject which is in a state of growth, it may be possible to hide, but it is impossible to avoid, all obscurity and vagueness; and original work ever consists in the attempt to overcome such obscurities. By purposely excluding everything that is vague from a physical treatise, we destroy all possibility of making the work useful in stimulating further research. There are two ways of dealing with difficulties: we may try to overcome them, or we may run away from them. Mr. Basset chooses the latter course, and though some of us might have wished him to be a little more venturesome, we gratefully accept what he has given us, and the above remarks only apply to certain parts of the book. After an introductory chapter, Mr. Basset treats of the interference of light. He follows the time-honoured custom of taking Fresnel's mirrors and the biprism as the simplest case of interference. The effects which are observed are seriously modified, however, by so-called diffraction effects, and we might perhaps have expected a book of this kind to have entered a little more fully into the subject. That the author avoids all reference to experimental details is a distinct advantage, and renders his book more lucid and valuable for reference. It is much to be wished the author's plan could be more generally followed, and that all lengthy discussions of instrumental details could be kept out of theoretical treatises, and relegated to separate books.

The diffraction of light is fully discussed in chapters iv., v., and xiii. Mr. Basset has followed safe guides in the treatment of his subject, and it is perhaps this part of the book which will be specially valuable to the teacher and student.

It is well that the phenomena of double refraction should be first approached without more allusion to the difficult subject of the constitution of the ether than is absolutely necessary, and this is perhaps most easily done by following, as Mr. Basset does, the historical method, and starting from Fresnel's deductions.

The colours of crystalline plates are, of course, treated in an important chapter, and it is worthy of note that Mr. Basset does not introduce the somewhat misleading distinction between the effects produced by parallel and by convergent or divergent beams. In the usual polariscopes a number of parallel beams pass through the crystalline plate in different directions. If the optical arrangement between the plate and the eye is such that these various beams enter the eye, we get the phenomena which are often called interference effects in divergent light, while if those beams only which make a small angle with each other are allowed to pass the pupil, we get the uniform tint described as the effect of parallel light. Both kinds of effects might also be produced if instead of parallel beams we had a number of pencils diverging from points in a plane close to the crystalline plate. In either case the eye is supposed to focus for an infinite distance, and the different appearance is only one of degree, depending on the extent of the angle between the different rays passing through the crystal and into the eye.

Mr. Basset enters fully into the consequences of the various hypotheses which have been made as regards the differences of density or elasticity of the ether in different media. The investigations referred to by him are, of course, of the utmost importance, but it should have been pointed out that as regards application to optics they are wanting in reality. We know enough now to be able to say that the medium does not behave like an elastic body, and in some form or other the electro-magnetic theory must be considered as established. It seems idle, therefore, to discuss whether the hypothesis of Green or of Neumann is most contradicted by experiment. It would have been perhaps worth while to bring out more clearly the fact that *no* elastic theory of the ether has yet been found satisfactory, and that if the electro-magnetic theory had not come to help us we should be in a very serious difficulty.

It is true, of course, that we are at present unable, and probably always shall remain unable, to discard the elastic theories, because the study of transverse vibrations can only be satisfactorily carried out with the help of examples in which we understand to some extent the mechanism by which the vibrations are propagated. But unless a writer chooses to follow a purely historical treatment, it would seem to be more satisfactory to separate completely the mathematical study of vibrations from the subject of optics. Treated purely as elastic vibrations we may usefully discuss what would happen at the boundary between two media having different elasticities or densities;

and such a discussion, though independent of optics, would be certain to have important applications in it, because its results would often still apply when translated into language of the electro-magnetic theory. The mathematical investigation of vibrations might be made more clear and definite when it is freed from the necessity of adapting itself to experimental verification.

Chapter xviii. is a useful one, dealing with "theories based on the mutual reaction between ether and matter," but we might have wished for a more satisfactory introduction to the electro-magnetic theory that is given in the last two chapters. The way in which the subject is approached may illustrate some of the remarks made in the beginning of this review. There is no doubt a very serious difficulty in explaining the fundamental notions underlying the theory, and Mr. Basset, instead of making an attempt to help the student over the difficulty, suddenly plunges into a series of equations, referring us to Maxwell's book for an explanation even of his symbols.

We have perhaps given an inadequate idea of the contents of Mr. Basset's book, which no doubt lends itself to criticism from the physicist's point of view, but which nevertheless fills a gap and possesses merits which will render it of great value to the student of optics.

Arthur Schuster.

THE APODIDÆ.

The Apodidæ: a Morphological Study. By H. M. Bernard, M.A. Cantab. (London: Macmillan, 1892.)

THE title of this little book is misleading. It is not a treatise on the Apodidæ, but a statement of the author's speculations on the relations of the Phyllopodous Crustacea and Branchiate Arachnida to the Chætopod Worms. The new observations recorded are few, and the most important, that as to the presumed hermaphroditism of *Apus cancriformis*, quite insufficiently set forth, and, so far as can be judged from the author's meagre statement, erroneous.

Mr. Bernard appears to be completely misinformed as to current views on the relationships of Apus to other Crustacea, and of that group, through it, to the parapodiate worms. Apparently he addresses himself to a lay audience, and poses, to start with, as the discoverer of a new and unsuspected agreement between the lower Crustacea and the Chætopoda. This may serve to excite the interest of uninstructed readers, but the zoologist knows that such pretensions are due either to defective acquaintance with the subject or to a want of candour on Mr. Bernard's part. The arguments by which Mr. Bernard endeavours to support his thesis are, many of them, those which have been effectively used by his predecessors in the same cause; others are new and remarkable only for their arbitrary character and the evidence which they give of the author's boldness in writing a book on a morphological problem. Mr. Bernard draws attention to the absence of developed articulations in the limbs of Apus as giving them a resemblance to the parapodia of Chætopoda. He states that this absence "has already been pointed out by Lankester and others, but its true significance does not seem to have been noticed." This is an incorrect allusion to my essays on the appendages and nervous system of Apus (*Q. J. Micr. Sci.*, 1881), and on Limulus an Arachnid (*ibid.*), which is the more to be regretted since they appear to have furnished Mr. Bernard with such of his theories as well as his facts as will bear examination. At p. 368, *loc. cit.*, my statement runs—

> "I have long been of the opinion which Prof. Claus appears to hold, that the appendages of the Arthropoda are homologous (or, to use a more distinctive term, 'homogenous') with the appendages of the Chætopoda, and on this account I consider it a proper step in classification to associate the Chætopoda with the Arthropoda and Rotifera in one large phylum—the Appendiculata."

Yet Mr. Bernard comes forward to tell us that he now for the first time draws attention to the true significance of the absence of articulations in the limbs of Apus, although (as he admits) this condition was especially noted and very carefully described eleven years ago by me in the same essay in which the above paragraph as to the relationship of Arthropoda and Chætopoda occurs. This is a sample of Mr. Bernard's method of claiming novelty for what he has to say when dealing with old materials. Frequently he asserts in strong language novel propositions which are purely speculative and of the truth of which no evidence is adduced. There is in no part of this little book any evidence that the author has made use of living or of well-preserved material, or has had any special opportunities of studying the genera and species of Apodidæ; nor does it appear that he has any experience as a zoologist which might give some weight to his fanciful conceptions. On the contrary, these crude speculations and dogmatic assertions are his first original contributions to zoological literature. I regret to be obliged to say that in my opinion (which I am called upon to express candidly in these pages) "The Apodidæ" is not a book which can be recommended either as a repository of fact or as a model of the method in which a morphological problem should be attacked.

E. Ray Lankester.

OUR BOOK SHELF.

Anatomy, Physiology, Morphology, and Development of the Blow-fly (Calliphora erythrocephala). Part III. By B. Thompson Lowne, F.R.C.S., F.L.S. (London: R. H. Porter, 1892.)

We have before us another section of Mr. Lowne's work, which has grown upon the author's hands, and will form two volumes instead of the one originally intended. Part iii. is occupied with the internal anatomy of the imago, embryonic development, histology, and the development of the imago. On each of these heads a great amount of information is supplied, and the author's statements are illustrated by many figures. As to the puzzling question of the way in which the alimentary canal of the blow-fly is developed, Mr. Lowne holds an opinion which is probably shared with no second person. What Voeltzkow and Graber take to be the proctodæum, and what Korschelt and Heider believe to be the amniotic cavity, Mr. Lowne calls archenteron. He is content, as he tells us in his preface, to await the verdict of posterity on such conclusions as this. We are content to wait too. The subject is too difficult for full consideration in this place, and it would be unfair to express a strong opinion without ample discussion of the evidence. It is not unfair, we think, to characterize many of Mr. Lowne's morphological speculations as simple mistakes. To compare an insect-embryo and its membranes with a Lamellibranch or an Ascidian in the extempore manner assumed so lightly by Mr. Lowne (p. 244) is not creditable. He tells us that he has no facts to guide him except the similarity of the form and disposition of the parts. Any reader who is not able to judge for himself should be very much on his guard when our author mentions Vertebrates or Ascidians, or indeed any other animals outside the class of Insects.

It is painful to speak with any disrespect of an author so laborious and so independent as Mr. Lowne. But these good qualities do not suffice to make a really good book. Advice will probably be thrown away, but we will offer one hint in the most friendly way. If Mr. Lowne before going to press would get his sheets revised by any cautious and well-informed zoologist, he would be saved from making statements which seriously impair his work.

L. C. M.

A Mendip Valley: its Inhabitants and Surroundings. By Theodore Compton. With Original Illustrations by Edward Theodore Compton. (London: Edward Stanford, 1891.)

This is an enlarged and revised edition of the well-known "Winscombe Sketches," and will be cordially welcomed by readers who can appreciate the presentation of natural facts in a poetic spirit. The author has spent the greater part of "thirty-three years of rural life" in the valley about which he writes, and every aspect of it he knows and loves. He tells much that is interesting, not only about the valley itself, but about the people who inhabit it, and about its archæological remains, its wild beasts, past and present, its birds, fish, reptiles, butterflies, and flowers. The style is simple and clear, and a certain charm is added to the writer's descriptions by the quaint reflections with which many of them are associated. An excellent chapter on the geological history of the Mendips is contributed by Prof. Lloyd Morgan. The illustrations are daintily conceived and executed, and harmonize well with the general tone of the text.

Key to Elementary Dynamics. By S. L. Loney, M.A. (Cambridge University Press, 1892.)

Those who are using the author's Elementary Treatise, whether they be teachers or students, will find this key very useful. The solutions to the examples are here worked out in full, so that even one who is going through the subject by himself will learn much in the nature of attacking problems by direct methods. The author's treatise is now so widely used that this key will come as a great boon to many.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

The Lightning Spectrum.

During the brilliant display of lightning on the evening of June 28, I took the opportunity of making some observations of the spectrum. The way in which the spectrum varied was very remarkable, some of the flashes giving apparently perfectly continuous spectra, while others gave a spectrum of bright lines, as already recorded by Kundt and others. The continuous spectrum appeared to be associated with the flashes of longest duration, which were accompanied by very little thunder, and the bright line spectrum with the more instantaneous flashes. Using a Liveing direct-vision spectroscope with a very accurate scale, I succeeded in measuring the positions of six lines in the green, all of which no doubt have been *observed* before, but in two cases at least the *positions* have not been previously measured. The wave-lengths of the lines observed were as follows—those determined by Vogel, Schuster, and Colonel John Herschel, being added for comparison:—

	Schuster.	Vogel.	Herschel.	Remarks.
(1) 5002	—	5002	5009	Brightest line
(2) 5168	5160	—	—	Rather dim
—	5182	5184	—	—
(3) 5350	5334	5341	—	Fairly bright
(4) 5430	—	—	—	Rather dim
(5) 5515	—	—	—	Fairly bright
—	5592	—	—	—
(6) 5675	—	—	—	Fairly bright

Other lines were seen both in the red and blue, but time did not permit any accurate determinations of their positions.

The lines (1) and (6) are undoubtedly the two brightest double lines of the air spectrum which occur in this region, but in the case of the other lines the coincidences are not so definite. The proximity of the line 5168 to the brightest carbon fluting (λ 5165) would suggest that it has its origin in the carbonic acid gas, which is always present in the atmosphere. The remaining lines do not appear to coincide with air lines, and their origins for the present are undetermined.

A. Fowler.

Royal College of Science, South Kensington.

On the Line Spectra of the Elements.

Prof. Runge has not improved the position he has taken up by the new instance of a motion which he brings forward in last week's Nature. The instance he gave in his preceding letter is a motion which, as I pointed out, could not take place within molecules. The motion he now gives is one which cannot even exist anywhere in nature. It would require a supply of power (energy per unit of time) increasing *ad infinitum*. The first instance he gave belongs to inapplicable kinematics, his new one to impossible dynamics. Neither has anything to do with the subject of my memoir.

He quotes the enunciation of a theorem from chapter iv. of my paper, but does not quote the sentence introducing that theorem, which would have made it plain that the motions spoken of in it are *motions which can take place within molecules and which can produce an undulation in the ether*, not the motions of a mere mathematical exercise irrespective of whether they are real or imaginary. The introductory sentence (p. 588) is in the following words:—"The motions of the electrons, the electric charges in the molecules, which are what excite the ethereal undulation, may be motions that are not confined to one plane. Accordingly *to study them* we must investigate what theorem corresponds to Fourier's theorem when the motion takes place along a line of double curvature." And then follows the demonstration and the enunciation quoted by Prof. Runge. In the foregoing words, in the introductory paragraphs of chapter iv. of my memoir, and in other passages scattered up and down through that chapter, I made it abundantly clear, as I thought, that I was dealing throughout *with a real physical problem of nature*, not engaging in mere mathematical exercises that travel into the infinite and impossible. I now see that I ought to have made more explicit statements upon this point for readers who would judge of each sentence apart from its context.

In order that a motion, $x = f(t)$, may be susceptible of treatment by Fourier's theorem, the following are conditions that must be fulfilled:—

1°. The motion must be recurrent, or capable of being approximated to by recurrent motions.

2°. The quantity represented by x must not become infinite.

3°. The quantity represented by t must not retreat.

I have been familiar with these limitations since I was a student, more than forty years ago. *They are known to all students.* I therefore thought it superfluous, and still think it ought to have been superfluous, to state them in my memoir. I thought it also irrelevant, *since none of the limitations could occur in the motions I was investigating*; and I wished to shorten my memoir by excluding all irrelevant matter. Prof. Runge, however, objects that I have not treated of violations of the first two of these conditions. He has not yet said that I ought also to have discussed the impossible dynamics in which the third condition would be violated.

This, however, was not his original position. He began (see his original article, NATURE, April 28, p. 607) by supposing that a motion from which light emanated cannot, if non-periodic, be investigated by Fourier's theorem; and he stated that in consequence of this he could not understand the decomposition of the motion of an electron within a molecule into a series of superposed elliptic motions. In NATURE for May 12, p. 29, and for June 9, p. 126, I demonstrated in two different ways that his supposition was a mistake. The other objection made in his original article, viz. that "a plausible suggestion about the movement of the molecules ought to explain more," is also a mistake. These are the two condemnations passed on my paper in his original article. Both these have been met. And the issues he has since raised are, I again submit, not *legitimate* criticism of a physical inquiry. To make them legitimate he would need to produce an instance of a motion *of the kind with which my paper deals* (*i.e.* a motion that can produce a spectrum) and which at the same time is not amenable to the method of analysis given in chapter iv. of my memoir. This he cannot do, for there are no such motions. In fact, the analysis effected by the spectroscope is *identical* with a part of that made by Fourier's theorem when applied in the way that I there point out. The spectroscope gives the periodic times in the different partials, the sum of the squares of their principal axes, and in some cases their forms; but it does not give the phases of the motions in them or the planes in which they lie. Prof. Runge almost admits that his criticisms do not succeed in impugning the value of my memoir as a contribution towards our knowledge of nature, for in his last letter he says, "I do not say, therefore, that Prof. Stoney's views on the cause of the line-spectra are wrong." This is very different from what he said in April.

G. JOHNSTONE STONEY.

July 17.

"The Grammar of Science."

MAY I, through your columns, point out to Prof. Pearson what seems to me a serious "antinomy," to use his own phrase, in his "Grammar of Science." The foundation of the whole book is the proposition that since we cannot directly apprehend anything but sense-impressions, therefore the things we commonly speak of as objective, or external to ourselves, and their variations, are nothing but groups of sense-impressions and sequences of such groups. But Prof. Pearson admits the existence of other consciousnesses than his own, not only by implication in addressing his book to them, but explicitly in many passages. He says (p. 59): "Another man's consciousness, however, can never, it is said, be directly perceived by sense-impression; I can only *infer* its existence from the apparent similarity of our nervous systems, from observing the same hesitation in his case as in my own between sense-impression and exertion, and from the similarity between his activities and my own."

With respect to the argument from the "similarity of our nervous systems," I may point out, *en passant*, that however many other people's nervous systems Prof. Pearson may have dissected, he has certainly never dissected his own, and that therefore this argument, which is several times repeated in the book, is worthless; all Prof. Pearson has to go upon is the external similarity of other people's bodies and activities to his own. But he maintains that our bodies and their activities are nothing but groups and sequences of sense-impressions. Consequently, if other consciousnesses are similar to his own, some of his groups of sense-impressions possess private consciousnesses, which themselves receive sense-impressions, among which, for example, are to be found Prof. Pearson himself! Thus Prof. Pearson's consciousness contains a number of parts, each of which contains, amongst other things, Prof. Pearson and his consciousness! Of course it would be impossible thus to refute a consistent idealist, who maintained that not only external things but all other consciousnesses were unreal and existed only in his imagination; but to recognize the reality of other consciousnesses is to recognize the reality of the means by which we become aware of them, which, as Prof. Pearson explicitly states, is the external aspect of men's bodies.

It is not difficult to find the way out of this difficulty. It is that, though we do not *know*, *i.e.* directly apprehend, anything about the external world but sense-impressions, yet in order to explain those impressions we frame the hypotheses of external, objective reality, and of the "ejective" reality of other consciousnesses, and since these hypotheses are successful in explaining most of our sense-impressions, we have come to believe that they are true. Indeed, I cannot seriously doubt that Prof. Pearson himself believes in them as much as anyone else. Only, if he were to acknowledge it explicitly, he would have to rewrite almost every page of "The Grammar of Science."

EDWARD T. DIXON.

12 Barkston Mansions, South Kensington,
July 14.

PROF. KARL PEARSON'S "Grammar" merits more justice than it has received from "C. G. K." It is a remarkable book which I have read with much interest. He tells us (p. 15) that "the unity of science consists alone in its method, not in its material," and therefore the method employed in this work on science acquires a special interest.

There are two points in respect to which his method seems to me to call for a few remarks—remarks which cannot be unwelcome, since his motto is "La critique est la vie de la science."

The first point concerns his own position and that of certain persons he freely criticizes. The Professor has scant patience with metaphysics, and says not a few hard things of those tiresome people the metaphysicians; and yet his own book is really a metaphysical treatise and he turns out himself to be an unconscious metaphysician *malgré lui*. This fact can hardly surprise anyone who has mastered what is really the scientific A B C; but in the present instance it is peculiarly amusing. For he, with great *naïveté*, ridicules Prof. Tait for being in the very same case. He is styled (p. 296) "the unconscious metaphysician, who groups sense-impressions and supposes them to flow as properties from something beyond the sphere of perception"; and we are further told that "the unconscious metaphysics of Prof. Tait occur on nearly every page of his treatment of the fundamental concepts of physical science."

The second point which seems to require notice is the way in which his method plays "fast and loose" both with the system he upholds and the system he most opposes.

He is an idealist of a kind. Again and again we are told that scientific laws are but descriptions of our feelings in conceptual shorthand. He speaks (p. 129) of "the whole of *ordered* nature" being "seen as the product of one mind—the only mind with which we are acquainted," and he tells us plainly (p. 130) that "the mind is absolutely confined within its nerve-exchange; beyond the walls of sense-impression it can logically infer nothing." It would be easy to multiply such quotations.

Now, of course the idealist can logically make use of ordinary language in describing co-existences and successions between his feelings. The Professor's distinctions (p. 114) between "physical and metaphysical supersensuousness" have been duly noted, as also his disclaimer (p. 57) of giving any real explanation of the physical side of thought. Nevertheless, none of these considerations appear to me to justify his dogmatic mode of speaking of things of which the senses can take no cognizance.

If he knows nothing but his own feelings, he cannot reasonably speak of their mode of formation, or of the manner in which one group of feelings acts upon another. Yet, referring to a sensory nerve, he writes (p. 51): "The *manner* [the italics are mine] in which this nerve conveys its message is, without doubt, physical," and (p. 81) "Beyond the brain terminals of the sensory nerves we cannot get." Stars are for him but "groups of feelings," and yet he writes about them as follows: "Among the myriad planetary systems we see on a clear night, there surely *must be* myriad planets which have reached our own stage of development, and teem, or have teemed, with human life" (p. 179).

Speaking of waves (p. 305) he tells us, "The wave *forms* for us a group of sense-impressions." But the wave is, for him, *itself* a group of self-impressions and so is a particle of protoplasm. Nevertheless he speaks (p. 413) of the probability that long stages of development preceded its existence, and "of the millions of years, with complex and varying conditions of temperature," needed in order "to pass from the chemical *substance* of life to that complex *structure* which may have been the first stage of organic being." He also declares (p. 425) the belief that "the evolution of organic nature is at the basis of human history is the *unswerving belief* of the present writer."

My present object is not to object to any of these statements, but simply to call attention to the complete accord which exists between the Professor's language and that of realism, or any of the materialists whose sayings he sometimes deprecates, and to note the practical outcome of such teaching as that of his metaphysical "Grammar."

Its Idealism is an Idealism of parade, to be brought out occasionally, above all to confound some rash or inexperienced advocate of Intellectualism and Common-sense. But ordinarily and habitually it most certainly is, as "C. G. K." affirms (NATURE, July 7, p. 222), "distinctly materialistic." This teaching is an excellent example of that "intellectual thimble-rigging"—I use the illustration as an apt one, but in no invidious sense—to which I have elsewhere (see *On Truth*, p. 135) called attention in greater detail.

In conclusion I would ask how Prof. Pearson's metaphysical system can be necessary or even useful for the progress of science?

What does it matter for science, provided we are all agreed about those things whereof the senses can take cognizance, whether or not we are convinced that something extended exists objectively? The Professor affirms (p. 215) that the man of science "refuses to project his conceptions, atom and ether, into the real world of perceptions until he has perceived them there." We are then so far agreed. We both welcome ether units, prime atoms, chemical atoms, molecules, molecular motion, ether rings, ether squirts, &c., as admirably useful working hypotheses, but not as things to be yet regarded as objective realities. If I am right, the utility for science of much of the Grammar is not easily to be recognized. But it has a very distinct metaphysical utility for the opponents of the system Prof. Pearson favours, and will no doubt meet with grateful recognition at the hands of some of them.

ST. GEORGE MIVART.

Hurstcote, July 16.

A "Viper" Bite.

As cases of poisoning from the bite of venomous reptiles are happily rare in this country, it may prove interesting to some of your readers if I relate my experience on this matter.

About a month ago I caught two snakes at Bickleigh, near Plymouth, and whilst examining one it "bit" or rather struck me on the lower part of the right thumb. I immediately sucked the puncture (it could not be called a wound) which bled a little, and tried to make light of the matter. A livid patch soon formed round the point, and the hand and arm commenced to swell. In a quarter of an hour I was unable to hold anything, and almost in a fainting condition. The first symptom (apart from the swelling) was a peculiar taste and a sensation of swelling in the teeth, then the tongue commenced to swell and became so large that I could hardly move it, my eyes seemed ready to start from their sockets.

In half an hour a terrible vomiting commenced, preceded by excruciating pains in the stomach and heart, and continued with the pains altogether for nine hours, every drop of liquid being ejected almost as soon as swallowed; there was also violent purging and complete suppression of urine.

There was practically no pain in the arm; altogether the painful symptoms lasted for about nine hours.

I did not lose consciousness at any time. The arm continued to swell for two days, and then it was nearly as large as my leg. After this the swelling subsided, but the arm did not return to its normal size until twelve days after the accident. After the swelling had gone I suffered very much from rheumatical pains, and in fact do so now, and the digestion was also very much impaired. The viper is a male, a little more than two feet long, and about one inch in diameter at the largest part. Colour, a dull yellowish brown on the upper side, with a zigzag black line running down the whole length. On the under side it is nearly black except at head, where it is pale yellow. I have kept the reptile now for nearly five weeks, and although well supplied with small frogs, &c., it has not eaten anything, and seems as lively as ever.

Cases of this kind, where the sufferer is able to record the symptoms, being rather unusual, is my excuse for occupying the space of NATURE.

Plymouth. W. A. RUDGE.

THE EDINBURGH MEETING OF THE BRITISH ASSOCIATION.

THE Association has already met three times in Edinburgh, in 1834, in 1850, and in 1871. With the success of the 1871 meeting fresh in the memories of many citizens, the Town Council and other public bodies have entered cordially into the local arrangements for the meeting. The local committee formed some twelve months ago and its sub-committees have been actively at work, and everything is now practically ready for the reception of the Association.

The number of members of the Association who have indicated their intention of being present, and of new members who have already joined, are such as to show that the meeting will be an exceptionally large one. More than fifty distinguished foreigners have accepted the invitation of the local committee to attend the meeting.

Reception and Section Rooms.—The reception rooms are in Parliament-square, adjacent to St. Giles' Cathedral and the City Chambers. The Parliament Hall, the various court rooms, the rooms of the Society of Advocates, and the new library and hall of the Solicitors before the Supreme Courts have been placed at the disposal of the committee, and have been so appropriated as to constitute an ideal suite of reception rooms, including secretaries' and treasurer's offices, post, telegraph, and telephone office, ticket office, enquiry office, reading room, writing room, ladies' boudoir, smoke room, and refreshment buffet. Many of the rooms lend themselves to decoration, and the arrangements are as excellent in taste as in convenience. The Section Rooms are all in the University buildings; Sections A, E, F and G in the old buildings, and B, C, D and H in the new buildings. These buildings are about two minutes' walk from one another, and about four from the reception rooms. The section rooms are all well adapted for the purposes of the meetings, and in connection with each there is ample accommodation for committee meetings, while provision has been made for the occasional subdivision of some of the sections. In the new University buildings a room has been set apart for a temporary museum, in which objects of interest, which are brought under the notice of any of the sections, may be afterwards placed so as to be more easily inspected than is possible during the meeting of the section. It is expected that this will prove a valued addition to the convenience of the meeting.

While light refreshments may be had at the buffet in the reception rooms, the principal luncheon room will be found in the Students' Union Club, situated between the new and old University buildings. In the club there will also be a ladies' room, smoking-room, billiard-room, &c.

Lectures and Entertainments.—The programme for the evenings will follow the usual lines:—On Wednesday Sir Archibald Geikie will assume the presidency and deliver an address; on Thursday, the Lord Provost, Magistrates and Town Council invite members and Associates to a *conversazione* in the Museum of Science and Art; the Lord Provost will receive and welcome guests to the City. On Friday, Prof. Milnes Marshall will lecture on "Pedigrees"; on Saturday, Prof. Vernon Boys will lecture to artizans on "The Photography of Flying Bullets"; on Monday, Prof. Ewing will lecture on "Magnetic Induction," and on Tuesday there will be a *conversazione* in the Music Hall on the invitation of the local committee.

Military bands will play in the Princes Street Gardens every afternoon during the meeting, and there will be organ recitals in the "Reid" music class-room. Afternoon entertainments will be given by the Royal Scottish Geographical Society, the Rector and Masters of the Edinburgh Academy, and by others.

Arrangements have also been made to form parties to visit Edinburgh Castle, Holyrood Palace, and Arthur's Seat; these visits will be in the afternoon.

Excursions.—The committee have prepared a long list of excursions. Among those for Saturday afternoon are geological excursions to North Berwick and Tantallon, and to the Pentland Hills; a botanical excursion to Gullane; a dredging excursion on the Firth of Forth; and excursions to such places of interest as the Land of Scott, the Fairfield Shipbuilding Works and Glasgow, the Pumpherston Oil Works, Dundee and the Firth of Tay, Stirling, Rosslyn, Dalmeny and the Forth Bridge, Newbattle Abbey, and Dalkeith Palace.

On Thursday, occasion is taken to visit places of interest further afield. St. Andrews, Dunkeld, Scone and Murthly (arboricultural), Croy (archæological), Dobbs Linn Moffat (geological), Moorfoot Waterworks, Hamilton Palace, Drumlanrig, Yarrow, Crieff, the Trossachs, Loch Lomond, the Firth of Clyde, are all brought within the limit of a one-day excursion.

Many of the more important manufacturing and other works in the city and neighbourhood are to be open to members, who will thus have ample opportunity of becoming acquainted with the trade of the district. Visits to the paper works at Penicuik or Currie, to the printing-ink works at Granton, and to the gunpowder mills at Roslin, will form pleasant short afternoon excursions. The printing offices of Edinburgh are of great interest, and many of them have made arrangements for the reception of visitors. Breweries, distilleries, biscuit factories, and hydraulic engineering works have all their special developments here, and are well worthy of visits.

Hospitality and Lodgings.—Perhaps the greatest difficulty that the local committee has had to face has been the date fixed for the visit of the Association. August is *the* holiday month in Edinburgh, and under ordinary circumstances the residential parts of the town are during that month entirely in the hands of the police. For many of the citizens, indeed, holidays are possible only in August. It has therefore been matter of congratulation to the committee dealing with this part of the work to find that many people intend to remain in town during the meeting of the Association and that they have been informed of a large number of offers of hospitality having been sent to visitors.

The hotel accommodation in Edinburgh is considerable, but the strain upon it in August is great. The local committee have secured for members of the Association a considerable number of rooms in hotels, and these are being rapidly allotted on application. Visitors who intend to live in hotels during the meeting will do well to make their arrangements early.

With regard to lodgings, probably no town is so well off as Edinburgh, and fortunately during August many of the best rooms are vacant. A register of lodgings has been opened at the local offices, and the secretaries are prepared to give assistance to visitors desiring to secure apartments. A provisional list of hotels and lodgings has been prepared and may be had on application. The principal clubs have offered to admit visiting members of the Association as honorary members during the meeting, subject to such conditions as are required by the constitution of the club.

Publications.—The programme of local arrangements will contain a hotel map of Edinburgh, a large scale map of central Edinburgh, including all the buildings used in connection with the meeting of the Association, and a general map of Edinburgh and Leith, on which all the works open to visitors are specially marked.

The "Excursions Handbook," published by the committee, gives details of the various transit arrangements and general sketches of the routes to be taken. It also indicates the nature of the interest attached to each excursion. The handbook will be illustrated by a special map of the South of Scotland and by section maps on a larger scale showing details of excursions.

F. GRANT OGILVIE.

THE ORIGIN OF LAND ANIMALS: A BIOLOGICAL RESEARCH.[1]

THIS remarkable and very unequal work, many-sided and heterogeneous, is worthy of careful consideration. It is not wanting in imagination, more or less disciplined, and it is loaded with information from the works of contemporary naturalists, now for the first time brought together in a single volume. One great merit it has of regarding plants and animals, not merely as forms of life, but as living forms: the machinery is exhibited to us in motion.

The title of the work scarcely conveys an adequate idea of its comprehensiveness; it might just as well have been styled "The Evolution of the Living World [for plants are not excluded from its universal purview], and the way it has been brought about."

The leading idea appears to be that a change from marine to terrestrial habitat has taken place much earlier in the history of the higher forms of life than is generally supposed, that the land from the early beginnings of geologic time has been peopled both with animals and plants, and has, more than the sea, been the great arena of progressive change. At the outset, the shore, where sea and land and air all meet and commingle, was the birthplace of life, and from it living forms have continually wandered in all directions—to the open ocean and the abyssal depths, to rivers, marshes, and dry land. From the Algæ, which are almost the only marine plants, the vegetable kingdom was derived. That this is characteristically terrestrial is due to the fact that vegetable protoplasm is less adaptive than animal. "Plants as land proprietors are the true conservatives;" hence, once on land always on land. The terrestrial character of plants offers a suggestive hint as to the place of development of the greater part of the animal kingdom: it also has been on land, but with more numerous offshoots to the sea. In terrestrial plants such as Myxomycetes—"the true Bathybius"—are the roots of the animal world; or if this claim be not admitted, and to Bacteria be assigned this place, a terrestrial origin remains unimpugned, since these organisms are predominantly inhabitants of the land.

The migration of marine animals may be direct, but more usually it is by successive stages, first through fresh water—"the great highway to land-life"—then to damp places, and finally to the dry land itself, which, however, at the time of migration may have been subjected to a damper and warmer climate than at present prevails. With change of medium progressive modification has been associated, for existence in the air makes three great demands on the organism, it must protect itself against being dried up, acquire new modes of respiration, and more substantial organs of support.

Many animals, ennobled by their response to these demands, have returned to the sea, and exercise dominion over it, undergoing, of course, fresh modifications, particularly of the respiratory organs; while others have retained possession of the terrestrial domain, adapting themselves to minor changes of habitat and climate. Thus far more groups of land-animals are derived from a terrestrial ancestry than we imagine, and the next-of-kin of orders now characteristically marine are less frequently than we suppose to be found in the sea, but must be sought for on the land. The whale and sea-turtle, land crabs and climbing fish, so far from being rare and exceptional cases, are instructive examples of great migratory movements and associated anatomical change.

The hypothesis not only supplies a needed stimulus, powerful enough to account for the evolution of the organic world, but at the same time it explains the futility of our search in marine strata for connecting links between leading types of life, since the most critical steps in evolution have been taken on the land, and terrestrial fossils are of the rarest occurrence.

---

[1] "Die Entstehung der Landtiere: ein Biologischer Versuch." Von Dr. Heinrich Simroth, Privat-docent an der Universität, Leipzig. Pp. 492, with 254 Illustrations in the Text. (1891.)

In illustration we may select the author's treatment of the Arthropoda, which have their origin in some ancient Annelid, probably a marine Polychæte, and not an Oligochæte, since no Arthropod possesses the red blood which the Oligochæta have acquired as an adaptation to land life.

The absence of cilia and a thoroughgoing chitinization, which are the most striking peculiarity of the Arthropoda, are a direct adaptation to land life; the chitinous envelope furnishing on the one hand protection against desiccation, and on the other organs of support, whilst its extensive development necessarily involves the disappearance of cilia, and the development of fresh contrivances for respiration.

Another important character common to the Arthropoda is the transverse striation of the muscle fibre; but transverse striation is generally admitted to be correlated with excessive functional activity, from which, according to the author, it results. Encase an animal in chitin, and its movements will, from the mechanical conditions of the case, be "acrobatic,"—to move at all it must move strenuously, by this excessive exercise transverse striation will develope in all the voluntary muscles, and "by correlation" in those of the alimentary canal as well. So much is the author impressed by the cogency of this reasoning that he regards the striation of the musculature as a direct indication of the terrestrial origin of the animal possessing it, and ventures to apply this formula to Sagitta, the direct development of which he gives as an additional argument for its descent from some terrestrial species.

The parapodia of the Annelida naturally gave rise to the appendages of the Arthropods, and it was while these were still short, scarcely-jointed stumps that the Trilobites branched off in one direction, converting all their parapodia into legs, and the Scorpions and Merostomes, which discarded their abdominal appendages, in another. The Crustacea, retaining like the Trilobites all their appendages, branched off at about the same level, and their connection with the Arachnida is confirmed by Jaworowski's recent observation of the exopodital and endopodital splitting of the appendages in Tarentula. A confirmation of the terrestrial habitat of the primitive Crustacea is suggested by the fact that the most archaic existing forms are the Branchiopoda, which still live in fresh-water and salt marshes, can survive drying up, and indeed seem to require it for the production of sexual eggs. The remarkable diversity of the respiratory organs in the Crustacea is another important piece of evidence, since it points to their having been acquired as secondary adaptations.

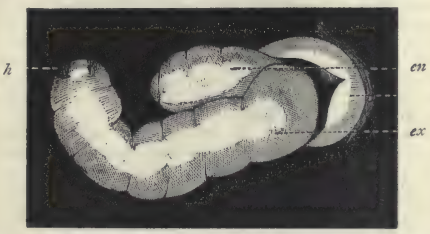

Fig. 1.—Pedipalp of an embryo of *Trochosa singoriensis*; *en*, endopodite; *ex*, exopodite; *h*, hairs (after Jaworowski).

Of Arachnoid forms, some entered the sea, probably the majority of the Merostomata and the Xiphosura, but Limulus still gives evidence of its original home, since it comes to the shore for begetting, and lays its eggs at the highest tide-mark.

No doubt the notion that the immediate ancestors of Limulus were land animals will excite scorn in prejudiced minds; but it is one that Balfour long ago suggested (the author does not seem to be aware of this), led to it probably by his recognition of the close relationship between Limulus and the Arachnoids on the one hand, and the Arachnoids and Insects on the other—the latter connection lately so much strengthened by Jaworowski's remarkable discovery of rudimentary antennæ in Tarentula. In this direction may be looked for a reconciliation of the views of Lankester and Lang.

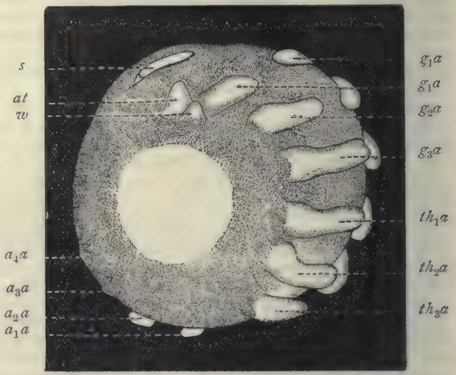

Fig. 2.

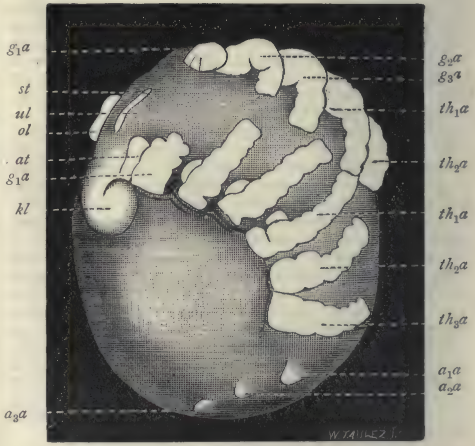

Fig. 3.

The mild surprise with which we learn that Trilobites and Crustacea were originally denizens of the land has scarcely given place to conviction before we encounter the chapter on fishes. We shall be prepared to find that these can claim terrestrial ancestry too. The earliest fossil vertebrates of which we know anything are the Placoderms; these were dwellers in the Old Red Sandstone lakes, and, as our author remarks, "from fresh water to the land is only a step." That the Placoderms were well able to take this step is proved by the character of their pectoral limbs, which, unlike the fins of fish, are provided with a transverse joint in the middle—"an elbow joint"; and this, while clearly helpful in walking, would not be well fitted for swimming. No doubt the animal was also a swimmer; the dorsal fin shows so much, but it was also a walker, travelling over hard, uneven ground; indeed, to this habit is attributable the turning up of the tail-fin (!), which formed the third point of support. A drawing, subscribed "original," representing Pterichthys "as it might have moved," is so full of unconscious humour that we are tempted to reproduce it. From such amphibious primitive vertebrates the fish branched off in one direction and descended to the sea—the swimming-bladder represents the original lung; in another direction proceeded the Stegocephala, the ancestors of reptiles, birds, and mammals. Primarily the Vertebrata are derived from Annelids, but the claim put forward for the Placoderms is more in harmony with Patten's view, connecting them with the Arachnoids; for the grave difficulties which beset this view, however, let Smith Woodward's trenchant criticisms be considered.

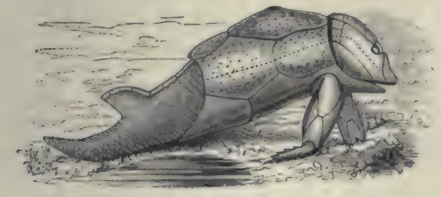

FIG. 5.—*Pterichthys*, as it might have moved. (Original.)

The main line of argument is followed into a number of collateral branches, all elaborately discussed. There is a powerful chapter on the strand fauna, in which are arrayed the great host of marine animals, including fishes, which temporarily leave the sea to breathe the air. This is regarded as a fact of profound significance, indicating a general tendency of the strand fauna to come on shore.

Recent investigations by Zacharias, Nusbaum, Chun, and others are made good use of in discussing the distribution of fresh-water fauna. Aërial transport, particularly by birds, is accepted as accounting for most of the facts. The survival of the transported forms is insured by the chitinous investment either of the animals themselves or more usually of their eggs. It is pointed out that most pelagic fresh-water species are provided with means of attachment: such are the spines of pelagic species of Daphnia, the abdominal processes of Bythotrephus, and the singular antennæ of Bosmina. Copepods which lay eggs which sink to the bottom are restricted in distribution; those which carry them about in egg-sacs are world-wide.

An attempt is made to prove that fresh water opposes some obstacle to the secretion of carbonate of lime; and though a comparison of the thickness of marine and fresh-water shells is far from bearing this out, yet some interesting results are elicited; as, for instance, the suggestion that the chitinous bristles of the young of *Paludina vivipara* are probably the last traces of originally calcareous spines.

In illustration of the various stages of land life, the Testacillidæ are cited as an interesting example of adaptation to a terricolous existence. *Daudebardia*, one of the family, begins life as a form precisely like a *Hyalina*, but with growth passes through the successive stages shewn in the figure (fig. 6) till it becomes the worm-like adult.

A good deal of space is naturally devoted to the subject of encystment, which is regarded as a protection against desiccation. In the course of this discussion an earlier origin is attributed to the Heliozoa than to the Radiolaria, since they do not possess the central capsule of the latter, which are consistently regarded as the marine descendants of an ancient fresh-water group related to Heliozoa. The suggestion is added that the withdrawal of plasma in the Radiolaria into the central capsule as a preliminary to spore formation is not really with a view to this event, but a reminiscence of encystment, which occurred in ancestral fresh-water forms. Bald suggestions such as this, and another which occurs in the work, to the effect that chlorophyll first acquired its fluorescence as the primæval sky cleared of clouds and permitted an extension of the solar light towards the violet end of the spectrum, should, from motives of prudence, have been omitted. A total *bouleversement* of accepted views on main lines of descent is sufficient for a great work without the added irritation of superfluous conjectures. Summer and winter eggs belong more or less to the question of encystment, and the author regards winter eggs as "an adaptation to small pools, and threatened destruction by drying up." This, like the statement that the chitinous shells of the eggs of pelagic Crustaceans were acquired as a protection against desiccation during their aërial flight, might have been expected from an ultra-Darwinian, but in an author who wishes to explain evolution by physical causes, and not by chance, it is less pardonable. "An adaptation to threatened drying up" is an expression which would please the metaphysicians, who have lately been contending that an effect may precede its cause.

FIG. 6.—*Daudebardia* in different stages of growth; on the right, youngest, on the left, oldest stages. The buccal mass is shaded. (Original.)

The bibliography at the end of the work will be found most useful, especially to Englishmen, who will find in it a guide to a great deal of interesting German literature; but it is without form, and this to a great extent is true of the work itself. There are citations to the number of 423, and more, not numbered, yet, although we have a long discussion on the relationship of Limulus to Scorpion, Lankester's work is not mentioned; with chapters on fresh-water faunas, no allusion to "The Origin of Fresh-water Faunas," by Sollas; W. Marshall, a German author, is set forward in the text as an authority on pelagic and coast faunas, and Moseley overlooked; titles are sometimes given without place or date of publication, a defect which becomes serious when periodical literature is referred to without mention of volume. The illustrations are numerous and excellent.

The author has produced a fresh and promising thought, but one cannot help regretting that he did not wait—like, say, Darwin—till it was full time for bringing forth.

W. J. SOLLAS.

THE PHOTOGRAPHIC MAP OF THE HEAVENS.[1]

THE first number of the second volume of papers published under the auspices of the Permanent Committee charged with the execution of the photographic map of the sky has made its appearance at a sad moment in the history of the undertaking. For simultaneously with its appearance is announced the death of him who, more than any other man, has contributed to its success, and brought it within the range of practical science. Admiral Mouchez has known how to secure not only the active co-operation of many astronomers, but also how to make them zealous in the great work, the arrangement of the details of which has occupied the last years of his life. He has awakened enthusiasm for the success of his scheme, and smoothed many difficulties which might have hindered its progress, and probably few undertakings of equal magnitude and equal importance, breaking new ground in many directions, have been got under way with less friction and fewer disappointments. We may well hope that the same sauvity and diplomacy which has characterized the conduct of the late Director of the Paris Observatory will be found in the counsels of his successor, and that a work begun in so much hope will be carried to a successful issue.

The papers in the volume before us can be brought roughly under two heads, both, notwithstanding the lapse of time from the inception of the scheme, betokening an initial stage in the preparation. One of the topics under discussion has for its aim the selection of a method which shall secure on the photographic plates, destined ultimately to furnish a catalogue, the impression of stars of the eleventh magnitude with certainty and uniformity; the other, a means of deriving the co-ordinates of the star images so impressed with the greatest facility and sufficient accuracy.

To deal with the second of these proposals first, we may remind our readers that whatever method of measuring the positions of stars on a plate may be adopted, the resulting co-ordinates must be purely differential, and probably referred to the axes of the réseau impressed upon the plate as a latent image, and developed under the same conditions as the stars themselves. To pass to the determination of R.A. and declination, a great deal of information, entirely independent of photography, will have to be made available. The readiest means of effecting this last step in the reduction, as it appeared to a committee of experts appointed to consider this question, was to determine by meridian instruments the absolute co-ordinates of six stars on each plate. It is needless to comment upon the magnitude of the labour thus undertaken, or at least contemplated. This preliminary work would demand a catalogue of some sixty or seventy thousand stars, most of them below the ninth magnitude and not found in existing catalogues. In order to give to each determination the necessary accuracy, it is desirable that each star should be observed twice in both elements and at two observatories. When we remember the length of time that the re-observation of Argelander's zones has consumed, and is still incomplete, we can form some estimate of the time that must inevitably elapse before the results of the photographic catalogue can be made available for astronomical purposes.

In presence of these difficulties, and many more which occur to the practical astronomer, we must be very grateful to M. Loewy for elaborating a scheme which, if it be found practicable, will materially shorten the time necessary for the production of the catalogue. M. Loewy proposes to avail himself of the fact that the plates are taken in two series, in such a manner that each corner of a plate in one series will form the centre of four other plates in the second series. When, therefore, the astronomer has determined the rectilinear co-ordinates of the stars on *one* plate relatively to the central lines of the réseau, each of these stars will belong in common to the plate considered, and to one of the four plates of the second series, partially covering the first. M. Loewy's scheme consists in making the stars on the four plates thus connected available for the reduction of the first. And, on paper at least, it is not difficult to extend the scheme still further, and to make the plates contiguous to these four contribute to the reduction of the original plate by means of an extended triangulation. In this way a plate would not be considered as an isolated fact, but a considerable area, of 36, 64, 100 or more square degrees could be woven into a harmonious scheme of reduction. And such a plan possesses this very obvious advantage, that on even a lesser area, as of 36 square degrees, we may well expect to meet a sufficient number of bright stars whose places are already so well determined that the reduction of the plates could go on immediately without waiting for the observations of the stars on the meridian. And independently of this evident advantage, it seems highly probable that two of the elements of reduction, viz. the orientation of the plate, and the value of the scale, will be determined more accurately, if the stars which are used for the derivation of these corrections are separated by a considerable distance, that is greater than a single negative would permit.

M. Loewy considers the various sources of errors and their necessary correction with all the detail required to submit the plan to practical application, and this is precisely the test that is needed. This appears to be also the opinion of Dr. Gill, expressed in a very cautious approval of M. Loewy's scheme, and he further quotes a remark of Prof. Auwers, which contains a very salutary caution. That astronomer points out that the reduction of the catalogue plates will be most accurately effected from the position of *faint* stars, rather than from bright ones. In that case since our present most accurate catalogues do not give the positions of the fainter stars, those catalogues will still need to be supplemented by many meridian observations. Dr. Sande Bakhuyzen, however, expresses the opinion that the zones of the *Astronomische Gesellschaft* will, when completed, furnish the necessary data for all reductions, or, at most, require additional observations in some portions of the sky, which he is able to point out from a careful examination of the number of the stars contained in these zones.

The second topic which has received much consideration in this volume is, as before mentioned, the adoption of a method to secure the registration of stars of the eleventh magnitude. It will be remembered that the International Congress of 1891 proposed to place in front of the object glass of the telescope, screens of fine metallic gauze, identical in manufacture, and of such construction that the amount of light impeded should be equivalent to two magnitudes: the coefficient 2·512 being employed as the ratio to express the relative brilliancy between two consecutive magnitudes. A committee was appointed to carry this plan into execution, but the report which this Committee has issued is unfavourable to the adoption of the method. The signatures of the Astronomer Royal, Prof. Pritchard, and the brothers Henry, are attached to this report; but M. Vogel, the remaining member of the Committee, has not found the reasons assigned by his colleagues sufficient to warrant the rejection of the scheme, and consequently his name does not appear. The President of the Permanent Committee thus sums up the case against the proposal. Light in traversing a metallic screen of bright threads and very narrow mesh, seems to experience, besides the ordinary effects of diffraction, certain modifications, whose cause is not yet explained, and which the Congress could not foresee when they framed the recommendation. This peculiar behaviour of the light demands further study, and renders the application of this means very difficult, if not useless, for the purpose for which it was proposed, since the discrepancies of the results obtained are greater than the error that an experienced astronomer would make in estimating stars of the eleventh magnitude.

---

[1] "Bulletin du Comité International Permanent," tome ii., premier fascicule.

The experiments on which this conclusion is founded are set out in considerable detail, and a careful study of these experiments ought to convince an unprejudiced critic that the committee was justified in advising the rejection of the screens as an adequate and efficient means of deciding upon stars of the eleventh magnitude. It should be stated that the gauze screens, identical in character, were furnished by Prof. Vogel, and though there is no mention of the experiments or processes which induced the Potsdam astronomers to select a screen of this particular obstructive power, it is to be presumed that in his photographic telescope they stopped the amount of light proposed by the Congress. It is not the least curious feature in the discussion (controversy would be far too strong a word to describe the courteous paragraphs in which the various astronomers set forth their reasons for dissent from the able physicist), that Prof. Vogel takes no part in it nor vouchsafes any information as to the principles by which he was guided in the selection, but leaves the onus of rejection entirely to his colleagues, who are thus placed at a disadvantage.

Prof. Pritchard, whose photometric researches permit him to speak with authority, has stated concisely the result of his experience. He found that on the ordinary astronomical telescope, achromatised presumably for D, the amount of light obstructed was equivalent to 2·4 mag., and on the photographic telescope, with a minimum focal length for G, the amount of light lost was not less than 2·8 mag. The Astronomer-Royal reports that the action of the screen on the Greenwich telescope is to stop 2·5 mag. This result was deduced by comparing the seventh and ninth magnitude stars of Argelander. Some further comparisons of the obstructed and unobstructed light of stars of the ninth and eleventh magnitude photometrically examined by Prof. Pritchard with the wedge photometer confirmed this result, and further proved that the scale of Pritchard and Argelander was in very satisfactory and close agreement. It will be necessary to return to this point. M. Henry at Paris offers results in close accordance with those of the two English astronomers just quoted. He finds that the screen proposed by M. Vogel as effective in his instrument stops between 2·5 and 2·7 mag. on the Paris telescope, and this effect is still further confirmed by some observations by M. Trépied, while M. Rayet at Bordeaux finds 2·7 mag. represents the effective action of the screen. Very different is the experience of M. Donner, of Helsingfors. His method of estimating the loss of light is different from that employed in the other cases, and is perhaps not without objection, but the result which he derives from his observations is that the light of a star in passing through the screen loses only 1·6 mag.

It is now necessary to describe very briefly the methods employed in the various observatories which have led to these discordant results, the more so as one eminent authority, Dr. Dunér, of Lund, who apparently holds a brief for Prof. Vogel, has taken exception to the results deduced. Leaving on one side the experiments conducted by MM. Henry and Trépied on artificial stars, and against which Dr. Dunér urges no objection further than that they are founded on artificial stars, we find that one principle pervades the examination conducted at Greenwich, Paris, Bordeaux, and Algiers. The several astronomers have determined what length of time is necessary to produce a blackened star disc of the same diameter from the same star with and without the screen. In this way it has been found necessary to expose for ten or eleven times as long with the screen before the object glass as without, and from this fact it has been inferred that the loss of light occasioned by the screen amounts to 2·5 or 2·6 mag. It is urged that if only two magnitudes were lost by obstruction, the necessary exposure would have been $(2{\cdot}512)^2 = 6{\cdot}3$, that required by the unobstructed object glass. Dr. Dunér remarks on this that those who have condemned the employment of the screens on these grounds have argued in a vicious circle, and to be logically correct it would be necessary to show that the intensity varies as the time of exposure or

$$it = \text{const.}$$

Against the accuracy of this law Dr. Dunér urges that reports of the observers themselves show three distinct proofs. In the first place (1) Dr. Donner states that only 0·58 mag. is gained by successively multiplying the length of exposure by 2·5; (2) that the Astronomer Royal proves that a gain of 1·7 or 1·85 mag. is secured by multiplying the length of exposure by 6·25; and (3) that MM. Henry have found that to obtain similar discs from stars of the 9·3 and 11·3 mag. the exposure has to be increased from 28sec. to 240sec. (1 : 8·6). These three experiments give instead of 2·512 respectively,

$$3{\cdot}28,\ 2{\cdot}69,\ 2{\cdot}93.$$

results apparently incompatible with the formula

$$it = \text{const.}$$

MM. Trépied and Henry reply at length and effectively to these strictures. They do not regard 2·69 and 2·93 as differing so greatly from 2·512 but that the discrepancy may be fully explained by inaccuracy and paucity of observations. The Helsingfors result (3·28) they refuse to accept as unequivocal evidence in the face of established facts. The method of Dr. Donner consisted in comparing photographs of the Pleiades, taken with and without the screen, with the map of M. Wolf, and marking the number and magnitude of the stars which have black or grey images. This method, as already hinted, does not seem to be entirely free from objection. Admitting that the comparison of the images was made, as we are sure it was, with all the care possible, there is still room for the varying exercise of individual judgment as to what constitutes a black and what a grey image, and the final result is likely to be less exact than a process based upon rigorous measurement.

The method employed by Prof. Pritchard is, perhaps, as free as any from objection or misinterpretation. He exposed the plate for *equal times* with and without the screen, and then measured the diameters of the resulting star discs. If two discs, produced, one with, and one without the screen, were found equal in diameter, then the effect of the screen is equivalent in photographic action to the original difference of magnitude between the two stars. This difference of magnitude was determined by the wedge photometer, and the only exception that can be taken to this determination is that the scale of the wedge photometer may not be accurately applicable. But here we have the distinct assertion of the Astronomer Royal, reiterated again by M. Trépied, that the Pritchard Argelander scales are in very satisfactory accord. This circumstance is the more gratifying for two reasons. First, because it is distinctly stipulated in resolution 19 (1889), "Chaque observateur devra s'attacher à obtenir sur ses clichés destinés au catalogue la grandeur 11·0 déterminée aussi exactement que possible *au moyen de l'échelle d'Argelander*." The maintenance, therefore, of the scale of Argelander becomes of paramount importance, and this one could scarcely hope to effect by means of the gauze screens. The second satisfactory point is, that Prof. Pritchard is endeavouring to secure uniformity in the photographed stars by distributing among the participating observatories small charts of particular regions of the sky on which are marked stars of the 9th and 11th magnitudes approximately. Naturally in the determination of the magnitudes of the stars on these charts, the scale of Argelander will be perpetuated, and inasmuch as the testimony of several astronomers is distinctly in favour of making use of these typical areas, it seems very probable that Argelander magnitudes will be prolonged in the catalogue work down to the faintest stars impressed.

NOTES.

The summer meeting of the Institution of Mechanical Engineers will be held in Portsmouth, and will begin on Tuesday, July 26. The following papers have been offered for reading and discussion, not necessarily in the order here given :—On shipbuilding in Portsmouth dockyard, by Mr. William H. White, F.R.S. ; on the applications of electricity in the Royal dockyards and navy, by Mr. Henry E. Deadman ; description of the lifting and hauling appliances in Portsmouth dockyard, by Mr. John T. Corner, R.N. ; description of the new Royal pier at Southampton, by Mr. James Lemon ; description of the Portsmouth sewage outfall works, by Sir Frederick Bramwell, F.R.S., Past-President ; description of the new floating bridge between Portsmouth and Gosport, by Mr. H. Graham Harris ; description of the Southampton sewage precipitation works and refuse destructor, by Mr. William B. G. Bennett ; description of the experimental apparatus and shaping machine for ship models at the Admiralty experiment works, Haslar, by Mr. R. Edmund Froude ; description of the pumping engines and water softening machinery at the Southampton water works, by Mr. William Matthews.

The half-yearly general meeting of the Scottish Meteorological Society was held at Edinburgh on Monday, July 18. The council of the society submitted its report ; and Dr. Buchan read a paper on variation in the annual rainfall in Scotland since 1800.

The Museums Association held its annual meeting in Manchester, at the Owens College, on July 5, 6, and 7, under the presidency of Prof. Boyd Dawkins, whose address we print elsewhere. Among those present at the meeting were Dr. Ward, Principal of Owens College, Prof. Flower, Prof. Miall, the Rev. Canon Hicks, Prof. Milnes Marshall, the Rev. H. H. Higgins, and Prof. Weiss. Mr. J. Willis Clark, the retiring president, was unfortunately prevented from attending. The following papers were read and discussed :—On the arrangement of botanical museums, by Prof. F. E. Weiss.—On the cultivation of special features in museums, by the Rev. H. H. Higgins.—Local museums of art and history, by the Rev. Canon Hicks.—On the Manchester Art Museum, by Mr. T. C. Horsfall.—On the preparation of picture catalogues, by Mr. Butler Wood.—On the colouring of the background of museum cases, by Mr. Edgar R. Waite.—On the best means of preserving vegetable structures, and on a collection illustrating the life-histories of the British Lepidoptera, by Mr. J. W. Carr.—On the exclusion of dust, by Mr. T. Pridgin Teale ; and library and museum legislation, by Mr. E. Howarth. Mr. Pacy and Mr. Ogle, who had been deputed by the Libraries' Association to attend the meeting, took part in the discussion of the last paper. A Committee of the Museums' Association was appointed to confer with the Libraries' Association on the possibility of taking steps to improve library and museum legislation. Most of the members of the Museums' Association who took part in the discussion were of opinion that the restrictions at present placed upon the action of Town Councils with regard to libraries and museums were unnecessary and obsolete. The meeting was a very successful one, thanks to the energy and good management of Mr. W. E. Hoyle and Prof. Milnes Marshall. The reception accorded to the Association by the authorities of the Owens College was of the most cordial nature, and the Association is indebted to Dr. Ward and several of his colleagues for much kindness. It was agreed to hold the next annual meeting in London under the presidency of Prof. Flower.

Mr. William E. Plummer has been appointed by the Mersey Docks and Harbour Board, director of the Liverpool Observatory, in the room of Mr. J. Hartnup, deceased. Hitherto this Observatory has done little more than regulate chronometers required for the port of Liverpool, but we understand that the Observatory will now be reorganized and made to play a more active part in observational astronomy, and one worthier of the equipment of the Observatory and the generous support the board accord to it.

Dr. W. H. Ince, Ph.D. (Würzburg), Demonstrator of Chemistry in University College, Liverpool, has been appointed Demonstrator of Physics and Chemistry in the Medical School of St. Thomas's Hospital.

Mr. A. H. Leahy, M.A., Fellow of Pembroke College, Cambridge, has been elected to the Professorship of Mathematics at Firth College, Sheffield. Mr. Leahy is a Mathematical Lecturer and Junior Bursar of his College, and is the author of several important papers on mathematical physics.

Mr. R. Elliot Steel, Senior Science Master of the Bradford Grammar School, has been appointed by the Technical Instruction Committee of the Corporation of Plymouth to the Head Mastership of the Science Department of their new technical schools, Plymouth.

The Master and Wardens of the Drapers' Company of the City of London recently gave £3000 towards the erection of the new technical schools attached to the Nottingham University College, and have now given a further sum of £1000 towards their equipment.

"Cook's Tours" are well known all over the civilized world, and vast numbers of Englishmen have been indebted to them for some of the brightest and pleasantest experiences of their lives. Everyone, therefore, was sorry to hear of the death of Mr. Thomas Cook, the founder of the system. He died at Leicester on Monday in his eighty-fourth year. Mr. Cook was a man of immense energy, and may almost be said to have had a touch of genius. At all events he had a very remarkable faculty for organization, and did much to foster among the British public a just appreciation of the advantages to be derived from foreign travel. Last year the jubilee of his firm was celebrated.

The volcanic forces of Mount Etna have continued in a state of violent activity. On the afternoon of July 14 it was stated, in a Reuter's telegram from Catania, that there were then eighteen openings in the mountain, of which nine were active. "The lava," said the writer, "is flowing in the direction of Nicolosi at the rate of 50 yards an hour. It has already passed the deposit of lava formed by the eruption of 1886. The flow towards Pedara is less rapid. Every hour the devastation increases, and the alarm of the inhabitants grows in proportion. Their terror is not lessened by the explosions and rumblings proceeding from the volcano." On July 15 a Reuter's telegram from Catania stated that the eruption was that day more formidable than ever. "The main crater is extending in size, and the showers of stones and masses of molten matter are continually increasing in volume, some of the projectiles being carried to a height of 1000 feet. Meanwhile, two fresh cones, 800 feet in height, have been formed, and from these streams of lava are constantly flowing in the direction of Nicolosi, from which they are now only about two miles distant. No immediate danger threatens the inhabitants of the village, but the destruction caused to the surrounding country goes on increasing." On July 16 and 17 telegrams to a like effect were despatched. On the latter date, indeed, it was stated that the eruption had been less active on the previous night, and the reports of the internal explosions less frequent and not so loud; but the volcano continued to throw up enormous blocks of incandescent rock together with clouds of steam. The lava stream had reached the village of Venatura, where it had destroyed several houses, besides doing enormous damage to the adjacent chestnut woods. On the 18th it was announced from Catania that during the previous night loud rumblings had continued, and that the discharge from the craters of Mount Etna had increased in violence, stones and ashes being projected to a height of over 1200 feet. In the morning the subterranean noises were less frequent and not so loud. At Patagonia, besides the volcanic explosions proceeding from Mount Etna, subterranean rumblings had been heard, while in the neighbouring naphtha lake, and the fountains of Vachella, gaseous eruptions had occurred. On the 19th, although the smoke proceeding from the craters was less dense, the eruption continued with renewed violence. The subterranean rumblings were more frequent and of longer duration, but not so loud as during the previous days.

ON July 15 it was announced from Naples that Mount Vesuvius had become active, and that lava in large quantities was pouring down the part of the mountain called the Atrio del Cavallo.

DURING the latter part of last week the weather over these islands was much disturbed by the influence of a deep depression which lay over the Baltic. The temperature was below 60° in the northern and below 70° in the southern parts of the kingdom, and the rainfall exceeded an inch in the south of Ireland. At the close of the week another depression appeared over the Bay of Biscay, and spread over our southern districts, accompanied by rain, while owing to the northerly winds the temperature continued very low, the maxima scarcely exceeding 60° in any part. In London on Sunday it did not exceed 55°, which, with about one exception, is the lowest daily maximum in July during the last half-century. During Monday night a deep depression advanced over Scotland from the northward, and travelled south-eastwards, accompanied by heavy rain, while on Tuesday increasing winds or gales were experienced on all our coasts, the wind direction varying from N.E. to N.W. and W. According to the *Weekly Weather Report* the rainfall for the week ending the 16th instant was considerably less than the mean in all the northern districts, while over the eastern, central, and southern parts of the kingdom there was a considerable excess, the amount being in many cases more than double the mean for the week. Temperature was below the mean in all districts excepting the Channel Islands; in the eastern and central parts of England the deficiency for the week amounted to from four to six degrees.

LAST week two despatches were received at the Colonial Office from Mr. Jerningham, Acting Governor of Mauritius, relative to the recent hurricane there. Mr. Jerningham states that the lives lost through the disaster were 1230, and the number of wounded still living 3167. Over sixty-two churches and chapels had been damaged or wrecked, and there had been a partial and enforced cessation of the celebration of Divine service throughout the island. The number of public buildings injured was 123, and the damage done to Government property was estimated at 286,807 rupees. The injury to the railways would cost about 55,435 rupees to make good. All the telegraph wires throughout the island were destroyed. About 16,976 houses and huts had been destroyed or damaged, exclusive of those in Port Louis, and about 170 sugar factories had been wrecked or injured. The task of repairing these disasters was one of great magnitude, and wholly beyond the unaided power of the colony. A later despatch states that in Port Louis 1453 houses, churches, and public buildings, representing a value of nearly five million rupees, had been wholly or partially destroyed.

THE *Kew Bulletin* for May and June contains several contributions which will be of great interest to botanists and to various classes connected with the industrial applications of botany. One of these contributions is a valuable report (with a plate) by Mr. George Massee on a disease that has attacked vanilla plants in Seychelles. In the same number are printed the second of the Decades Kewenses Plantarum Novarum in Herbario Horti Regii conservatarum, and the second decade of new orchids. An excellent illustration of the way in which the authorities at Kew seek to promote industry is afforded by a correspondence on Sansevieria fibre from Somali-land. The increased attention devoted to the production of white rope fibres in the Western tropics appears to have had a stimulating effect in the East Indies, and now the production of fibre from *Agave vivipara* in Bombay and Manila is followed by a fibre obtained from Somaliland from a singular species of Sansevieria. This fibre was first received in this country as an "Aloe" fibre. It was soon noticed, however, that it possessed characteristics differing from all ordinary "Aloe" fibre, and a request was made to the Foreign Office that Colonel Stace should be invited to obtain for the Royal Gardens a small sample of the fibre, a large leaf from the plant yielding it, and, if possible, a few small plants for growing in the Kew collection. In due time the specimens arrived in excellent order, and it was found that the fibre is one of the many so-called Bow-string Hemps, and probably yielded by *Sansevieria Ehrenbergii*, a plant first collected by Dr. Schweinfürth. Little or nothing was known of it until it was described by Mr. J. J. Baker, F.R.S., in the Journal of the Linnean Society, vol. xiv., p. 549. Its locality is there stated as "between Athara and the Red Sea." The plant is described in a letter to the Foreign Office, written by Mr. D. Morris, as a very interesting one, and he adds that its existence as a source of a valuable supply of fibre will be sure to awaken attention among commercial men in Great Britain. Messrs. Ide and Christie, writing to Mr. Morris, speak of the fibre as an excellent one of fair length and with plenty of "life." "In character," they say, "it strongly resembles the best Sisal hemp, with which we should have classed it but for your statement that it is derived from Sansevieria. With the exception of its colour, its preparation is perfect, and even as it is, we value it to-day at £25 per ton. We are of opinion that if care were taken to improve the colour a considerably higher price would be readily attainable, perhaps as much as £50 per ton, if a pure white fibre could be attained without loss of strength and lustre."

Among the other contents of this number of the *Kew Bulletin* is an account of the fibre industry in the Bahamas, communicated to Kew by Sir Ambrose Shea, Governor of the Bahamas. Extracts from a report by Mr. A. White, a naturalist attached to the staff of Mr. H. H. Johnston, H.M.'s Commissioner and Consul-General for the territories under British influence to the north of the Zambesi, throw welcome light on the botany of Milanji in Nyassaland. Mr. N. E. Brown contributes notes on the botany of plants yielding Paraguay tea. There are also sections on the Nonnen pest in Bavaria, the prickly pear in Mexico, and the Palmyra bass fibre.

The collection of hardy bamboos and allied plants having outgrown the space allotted them in the beds near the Temperate House of the Royal Gardens, Kew, a new garden has been made for them in a wood near the Rhododendron Dell. Of this garden the *Kew Bulletin* gives the following account:—It is in the form of a shallow depression with sloping banks 12 feet wide and a central pear-shaped bed 125 feet by 75 feet. To make it, the surface soil had to be removed and the gravel taken out to a depth of about 3 feet. A large quantity of new soil and manure was added so that the bamboos have now a good depth of rich soil. Two new paths leading to the Bamboo Garden have been made, one from the Syon vista and the other from the Stafford walk. The bamboos planted in the garden are:—*Arundinaria Fortunei* (Bambusa Fortunei), *A. japonica* (Bambusa Metake), *Bambusa albo-striata*, *B. gracilis*, *B. nana* (Hort), *B. palmata*, *B. plicata*, *B. pumila*, *B. tessellata*, *B. Veitchii*, *Phyllostachys bambusoides*, *P. nigra*, *P. Quilloi* (Bambusa Quilloi), *P. violescens* (Bambusa violescens), *P. viridi-glaucescens* (Bambusa viridi-glaucescens), *Thamnocalamus Falconeri* (Bambusa Falconeri), and several others unnamed. Besides bamboos it contains such plants as *Arundo*, *Eulalia*, *Crinum*, *Funkia*, *Yucca*, &c. It is also intended to bring together in this garden a number of the coarser growing monocotyledonous plants which can be grown in the open air at Kew.

According to an official "Notification of the Trustees of the Schwestern Fröhlich Stiftung" at Vienna, certain donations and pensions will be granted from the funds of this charity this year in accordance with the will of the testatrix, Miss Anna Fröhlich, to deserving persons of talent who have distinguished themselves in any branch of science, art, or literature who may be in want of pecuniary support, either through accident, illness, or infirmity consequent upon old age. The grant of such temporary or permanent assistance in the form of donations or pensions is, according to the terms of the foundation deed, primarily intended for Austrian artists, literary men, and men of science, but foreigners of every nationality, English and other, may likewise participate, provided they are resident in Austria. Particulars may be obtained at the Austrian Embassy, London.

Mr. T. S. Shearmen, of Brantford, Canada, has recently issued a pamphlet, in which he claims priority in the discovery of the fact that the influence of sun-spots on terrestrial magnetic conditions depends upon the positions of the spots on the sun's disc as seen from the earth. He states that he has succeeded in convincing Prof. Young that this claim is justified. His observations have led him to believe that, in the great majority of cases, magnetic disturbances are most numerous when spots are at or near the eastern limb. In many cases, however, especially when the spots were very large, the disturbances have been greatest when the spots were near the central meridian; but even then it is stated that on nearly every occasion in which this has happened, another spot was making its appearance on the eastern limb. M. Veeder (Nature, vol. xlvi. p. 29) also concludes that in order for a solar disturbance to have its full magnetic effect upon the earth, it is necessary that it should be at the sun's eastern limb, and as nearly as possible in the plane of the earth's orbit.

In the tenth annual report of the Fishery Board for Scotland a striking instance is given of the advantage which persons engaged in the fishery industry derive from the electric telegraph. The Orkney officer reports that on Saturday morning, August 22, a large shoal of herrings was discovered about three to seven miles off the island of Stronsay by a few boats which happened to be at sea. Having ascertained the position of this shoal the officer wired the particulars, for the fishermen's information, to all the stations in Orkney. On the Monday following every boat employed in the herring fishery in Orkney was on the fishing ground indicated, with the result that the heaviest fishing ever obtained in one day in Orkney (for the number of boats employed) was landed on Tuesday, the average catch for the whole fleet being fifty crans. The number of boats fishing was 108, and their total catch was 5400 crans, valued at £3240, a large proportion of which would have been lost but for the telegraph. Wick fishermen having also been apprised of the circumstance, a number of the Caithness boats had good takes on the same ground and landed them at Wick. Consequent upon such a heavy and unexpected fishing, additional coopers, gutters, packers, barrels, and salt had to be immediately sent for from Wick so that the herrings might be cured while they were in a fresh state, and this was accomplished by means of the telegraph.

An interesting exhibit of tobacco will be sent from Kentucky to the Chicago Exhibition. There will be exhibits of different varieties of plants in various stages of growth, and illustrations of the manner of shipping and handling "the weed" from the time the seed is put in the ground until the final product is ready for use. The various ways in which tobacco is used in manufacture will also be illustrated.

During the last few years much has been said about the supposed European origin of the so-called Aryan race. The honour of having first suggested this theory is usually attributed to Dr. Latham, but, according to Dr. D. G. Brinton, it really belongs to Omalius d'Halloy. In *Science* (June 24), Dr. Brinton refers to a paper in the *Bulletins de l'Académie Royale de Belgique*, tome xv., No. 5, May, 1848, entitled "Observations sur la distribution ancienne des peuples de la race blanche," in which Omalius begins by speaking of a series of notes presented by him to the Academy from 1839 to 1844. In these notes he had sought to prove that the Asiatic origin of the white race had never been demonstrated. Having recorded this fact, he proceeds "to discuss the evidence, physiological, historical, and linguistic, which had been thought to show that the Indo-European peoples originated in Asia; and combats it at every point, marshalling his arguments to prove that the true white type is distinctly European; and that the ancient Sanscrit and Zend are in no wise maternal languages of the Indo-European stock, but merely sisters of the Greek, Latin, and ancient German." The earliest date at which Dr. Latham expressed similar views was 1851.

Some suggestive notes on Fuegian languages, by Dr. D. G. Brinton, were read lately before the American Philosophical Society. He refers to a very early Fuegian vocabulary, collected by the French navigator, Jouan de la Guilbaudière, during a sojourn of eleven months in the Straits of Magellan during the year 1695. It includes about three hundred words and short phrases, and no part of it has been published. The MS. copy of it in Dr. Brinton's possession he owes to the courtesy of M. Gabriel Marcel, the Librarian of the Geographical Section of the National Library of France. As M. Marcel intends to give it publicity in the Compte-rendu of the Congress of Americanists, Dr. Brinton contents himself with illustrating its character by a limited selection of words. These show that the basis of the tongue is Alikuluf, and it differs, he says, scarcely more from the Alikuluf of the present generation than do between themselves the vocabularies of that tongue by Fitzroy and Dr. Hyades in the present century. A few words belonging to the Tsoneca and the Yahgan may be detected, probably introduced by trading natives.

The new number of the Journal of the College of Science, Imperial University, Japan (vol. v., Part 1), contains studies on reproductive elements, by C. Ishikawa; further studies on the formation of the germinal layers in Chelonia, by K. Mitsukuri; papers on the development of *Limulus longispina*, and on the lateral eyes of the spider, by Kamakichi Kishinouye; a paper on the formation of the germinal layers in Petromyzon, by S. Hatta; and notes on a collection of birds from Tsushima, by I. Ijima. The papers are most carefully illustrated.

We have also received the second part of the first volume of "Iconographia Floræ Japonicæ," by Ryōkichi Yatabe (Tokyo: Z. B. Maruya and Co.). The work consists of descriptions, in Japanese, of plants indigenous to Japan, with figures.

Mr. T. E. Buckley contributes to the current number of the Annals of Scottish Natural History some interesting notes on the vertebrate fauna of Sutherland and Caithness. The object of the notes is to bring the fauna of these two countries up to date. One bird, the ruff, is new to the Sutherland list, and Mr. Buckley is able to show the spread of certain other species such as the stock dove, tree pipit, &c. Eagles still hold their ground fairly well, but other birds of prey show a decrease. This, the author thinks, is only what might be expected, but it is sad, he says, to see how the hen harrier is rapidly approaching extermination. Plantations are growing up, and increase the number and breeding areas of certain species. When staying at Badenoch, he has been repeatedly struck in the autumn with the attraction which a few (say three or four hundred) small firs, a garden, and an acre or two of cultivated ground, have for migrating birds. Constantly in the early October mornings he has seen flocks of small birds, such as greenfinches, chaffinches, &c., descend into these trees, rest for a short time, then, with an unanimous twitter, rise up and pursue their onward course. As a rule everything was quiet for the day by nine o'clock.

At the meeting of the Field Naturalists' Club of Victoria on May 9, Mr. T. S. Hall read an interesting note on musical sands. While on a trip to Phillip Island at Christmas time, Mr. Hall was struck by the musical note given out by the sea sand when walked over. He had never noticed this phenomenon before, though it occurs not uncommonly in other parts of the world. His first idea was that the sound was caused by the india-rubber soles of his shoes, but he found he could get the musical note by striking the sand with his hand, or by drawing a stick rapidly over the surface. The sound was produced only where the sand was dry, and resembled almost exactly that caused by drawing the finger rapidly over a piece of corded silk. On making the sound by skating over the surface, he found that the note could be detected at a distance of forty paces. The sands were musical wherever he tried them about Cowes, and the only person to whom he spoke who had noticed the phenomenon said he had also noticed it at San Remo. Mr. Hall has since tried the sand at Geelong, Barwon Heads and Warrnambool without any result. He referred to the theories of Mr. Carus-Wilson on the one hand, and Dr. A. A. Julien and Prof. H. C. Bolton on the other, and expressed a hope that some attention would be given to the subject in Australia.

In the latest quarterly statement of the Palestine Exploration Fund it is said that considerable progress is being made with the Akka-Damascus Railway, the route of which, after various expensive surveys, has been definitely decided upon. The line chosen is practically that first suggested by Major Conder, R.E., several years ago. Beginning at the great fortress of Acre, the railway will run down the plain of Acre parallel with the sea, throwing out a branch to Haifa, at the northern foot of Mount Carmel, and thence to and across the plain of Esdraelon, passing near Nazareth to Shunem and Jezreel, and through the valley of Jezreel, skirting the slope of the hills, to the River Jordan, which will be crossed within sight of Bethshean. The Jordan here offers exceptional facilities for the erection of the railway bridge, consisting of two spans. Not only are the two opposite banks of the river formed of solid rock, but the centre of the river contains a large block of similar rock, from which each span of the bridge will be thrown to the east and west bank respectively. From the Jordan the railway will ascend the slope of the Jaulan Plateau, along the crests that close the eastern shores of the Sea of Galilee, this ascent constituting the only difficult portion of the line, but which the surveys now made show to be much easier of accomplishment than was originally anticipated. The plateau near El 'Al being reached, an easy gradient will carry the line by Seil Nawa and Kesweh to Damascus. Passing through the finest plains of Western and Eastern Palestine, the railway will be one of great importance. The authorities of the Palestine Exploration Fund are of opinion that its construction can hardly fail to lead to important archæological discoveries, and the committee hope to make arrangements for obtaining full information respecting these.

The additions to the Zoological Society's Gardens during the past week include a Pig-tailed Monkey (*Macacus nemestrinus*) from Java, presented by Major Day; two Red-handed Tamarins (*Midas rufimanus*) from Surinan, presented by Mr. J. J. Quelch, C.M.Z.S.; two Sœmmerring's Gazelles (*Gazella sœmmerringi* ♂ ♀), three Egyptian Gazelles (*Gazella dorcas* ♂ ♀ ♀) from Suakim, presented by Colonel Holled Smith, C.B.; a Red Deer (*Cervus elaphus*), European, presented by Mr. J. Newton Hayley; a Slender-billed Cockatoo (*Licmetis tenuirostris*) from South Australia, presented by Mrs. Duppa; a Rough-eyed Cayman (*Alligator sclerops*) from South America, presented by Dr. Rudyard; two Dwarf Chameleons (*Chamæleon pumilus*) from South Africa, presented by Mr. E. Windgate; a Common Chameleon (*Chamæleon vulgaris*) from North Africa, presented by Mr. J. Cornwall; two Green Lizards (*Lacerta viridis*), two Green Tree Frogs (*Hyla arborea*), European, presented by Count Pavoleri, F.Z.S.; a Horned Lizard (*Phrynosoma cornutum*) from Texas, presented by Mr. Conrad Kelsal; a West African Python (*Python sebæ*) from West Africa, received in exchange; six Mandarin Ducks (*Æx galericulata*), five Summer Ducks (*Æx sponsa*), seven Chilian Pintails (*Dafila spinicauda*), six Australian Wild Ducks (*Anas superciliosa*), a Variegated Sheldrake (*Tadorna variegata*), four Upland Geese (*Bernicla magellanica*), a Cheer Pheasant (*Phasianus wallichii*), a Himalayan Monaul (*Lophophorus impeyamus*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

A New Nebulous Star.—Mr. Barnard, in *Astronomische Nachrichten*, No. 3101, gives a brief account of a new nebulous star that he found when photographing, on May 31 last, a region situated in the Milky Way, 18h. 10m., – 20°. This star (B.D. – 19°·4953), when examined (visually) with his 12-inch, was quite devoid of nebulosity owing to the brightness of the star in question, but the photograph showed a faint nebulosity of about 15′ in diameter symmetrically surrounding it. A former photograph taken in 1889, July 28, indicated also the same nebulosity. The exposure in the former case was of 3h. 29m. duration, a Willard lens of 6-inch aperture being used. The position of the star for 1860 was R.A. 18h. 9m. 23·2s., Decl. − 19° 42′·7.

ATMOSPHERIC DEPRESSIONS AND THEIR ANALOGY WITH THE MOVEMENTS OF SUN-SPOTS.—The solar photosphere, although so different in chemical composition from our own atmosphere, yet affords us many points of resemblance with regard to its general circulation. One special analogy, and that a comparison of the motions of storms here with those of spots on the solar surface, is treated of in the July number of *L'Astronomie* by M. Camille Flammarion. In this article he has brought together sufficient observations to trace out the paths of many of the most violent storms that have from time to time visited Europe generally. The first storms which he gives are those which occur in the Atlantic; their general direction of motion seems to be from south-west to north-east, pursuing generally the path of the Gulf Stream. Their centres, when traced on a map, seem to just graze the shores of the British Isles, France very rarely being reached by them. From observations made on land, and more especially from those at Paris, M. Flammarion remarks that certain curves with regard to these storms seem to offer many analogies to solar spots; this is so not only for the regular displacements, but even for those which at first sight seem to be totally void of all regularity. The diagrams which he gives, showing both the paths of the storms and those of sun-spots, afford most interesting comparisons and seem to confirm the view suggested by M. Faye that the constitution of spots resembles somewhat that of the cyclones with which we are familiar.

YALE COLLEGE OBSERVATORY REPORT.—In this report, submitted by the Board of Managers to the President and Fellows of the Yale Observatory, Mr. Brown makes us acquainted with the present condition of the Observatory generally, while Dr. Elkin gives an account of the work done by the heliometer during the past year. The satellites of Jupiter formed the principal object of work from July 1891 to January 1892, 570 complete measures of their relative positions having been obtained on 114 nights. Dr. Chase, with the same instrument, has been measuring the cluster in Coma Berenices, securing from 18 to 20 measures for each of the 32 stars, besides determining the required data for the reduction-constants. In the work on the parallaxes of the first-magnitude stars in the northern hemisphere, the 100 sets of measures of each of the ten stars have not yet been fully completed, but the following table shows the results obtained up to the present, Dr. Elkin thinking that it will require two more years before the final results can be published:—

Star.	Parallax.	Prob. Error.	No. of comp. stars.	No. of Sets.
	″	″		
α Tauri	+ 0·101	+ 0·022	6	65
α Aurigæ	+ 0·095	0·021	5	51
α Orionis	+ 0·022	0·022	6	48
α Canis Minoris	+ 0·341	0·020	6	48
β Geminorum	+ 0·057	0·021	6	48
α Leonis	+ 0·089	0·026	10	43
α Bootis	+ 0·016	0·018	10	89
α Lyræ	+ 0·092	0·019	6	67
α Aquilæ	+ 0·214	0·023	10	46

GEOGRAPHICAL NOTES.

THE condition of affairs in Uganda, of which much has recently been made in home and foreign newspapers, is a question rather of politics than of geography; yet problems of a geographical kind are involved in it. So far the progress of civilization amongst the Waganda has served only to introduce new elements of dissension, and the attempts to carry out the policy of preventing the sale of spirits, firearms, and ammunition have only been partially successful. Scientific exploration in a country so unsettled must necessarily be suspended. If the British occupation is to be productive of benefit either to British trade on the one side or to native interests on the other, the firm and impartial rule of Captain Lugard and Captain Williams must be maintained and reinforced. The urgent request which these officers have made for additional white assistance demands all the more attention since the garrison under their control has been swelled by the survivors of Emin's force in Equatoria.

ALTHOUGH, as announced in NATURE (p. 230), Captain David Gray's Antarctic expedition has fallen through, it is satisfactory to know that three Dundee whalers, which are shortly expected back from the Arctic "fishing," will be refitted immediately and despatched about the beginning of September to the Falkland Islands, and as far to the south as may be necessary in order to get a cargo. The proposed cruise is to be purely commercial, and it is not likely that any exploring work will be done. It is probable that berths will be available on board for two or more scientific men, who should have good opportunities of collecting natural history specimens. The experience of the whale-ships will be valuable in supplying hints for the equipment and route of the great Antarctic expedition which under some European flag cannot be long delayed.

DR. OSCAR BAUMANN, charged with the survey of a road to the Victoria Nyanza, reached the shores of that lake in April, after an unprecedentedly rapid journey from the coast. From the *Times* report of a letter written by Dr. Baumann from Kadoto, we learn that the route, after passing around Lake Manyara, struck across an unknown stretch of country in which a new lake of large dimensions was discovered. Even in Africa few lakes of such magnitude can now remain unknown, at least from native reports. Lake Eiassi lies on the plateau south-east of Victoria Nyanza, and from the report of the neighbouring Masai, it seems to be about ninety miles long, while the breadth of the northern portion, along which Dr. Baumann marched, varied from eighteen to thirty miles. This lake is presumably filled with fresh water, but no outlet is mentioned. It is interesting, however, to find native reports of a great river flowing in on the western side, which may be confidently identified with the Wemberi, a river shown on recent maps as flowing north-eastward from the border heights of Unyamwesi, and losing itself on the plateau. It is possible that the new lake may discharge into the Victoria Nyanza by the Simiu river, the head waters of which have not previously been explored.

THE recently founded New Zealand Alpine Club has published the first number of its *Journal*, devoted to the exploration of the glaciers and peaks of the Southern Alps. The magnitude and difficulty of these snow mountains of the south has hitherto been very inadequately realized.

THE MUSEUM QUESTION.[1]

GENTLEMEN of the Museums Association,—In taking the chair which was so ably filled by my predecessor at Cambridge, I must first of all give you a hearty welcome on the part of the Committee of the Manchester Museum. There is to my mind a singular fitness in the selection of Manchester as a place of meeting after Cambridge. At Cambridge you had the opportunity of studying the various museums which have in the course of time naturally grown out of the development of that ancient seat of learning. In Manchester you will see the collections which have been gathered round Owens College, which represents the newest University development in this country. The genius of the place has left its mark in both. In Cambridge the collections are, as they should be in a region of academic calm, free from trade-winds, arranged mainly, if not entirely, with an eye to University students, and not for the general purposes of a miscellaneous public. In this busy centre of movement and commerce, you will find that the principle of arrangement is twofold. It first aims at meeting the needs of the University students, and of the Mechanics' Institutes, and schools, and other educational bodies, which are daily being drawn closer to Owens College, and next at the instruction and enjoyment of the general public. Our collections are for the most part older than the college and have been absorbed from without into our educational centre.

The problem which we have attempted to solve is this: How to arrange and organize collections which are in part as old as the second quarter of this century, so that they may become valuable in the new learning and at the same time put an outline of the history of nature within reach of the people. This problem, as we all know, is not an easy one. It has, however, to be faced in most of the museums of this country. Whether it has been solved or not in Manchester, it is not for me to say. Prof. Huxley, in addressing us some years ago on the question of technical education, said that he did not know exactly what shape it should take, but that Manchester was a good place in which to make an experiment for the good of the Commonweal. *Fiat experimentum in corpore Mancunensi.* The result of our experiment in museum organization is here and speaks for itself.

---

[1] Address to the Museums Association, Manchester meeting 1892, by the President, Prof. Boyd Dawkins, F.R.S.

Before, however, I deal with this special attempt to meet the needs of Manchester I must touch on the general question of museums.

The Museum Idea and its Place in Culture.

A museum was to the Greeks a place haunted by the Muses, and in a secondary sense a building in which liberal studies were carried on such as that at Alexandria, which was a great University endowed by the State, divided into colleges, and frequented by men of science and letters. This museum included picture galleries and statuary, and it is not at all improbable that it contained also collections of Natural History. Aristotle, it must be noted, made vast collections, which he used in his history of animals, by the aid of his friend Alexander the Great, and it is hard to believe that the impulse which he gave to the study of natural history should not have been felt in Alexandria, where his memory was venerated. With the destruction of this museum in the days of Aurelian in the last quarter of the third century after Christ, the name as applied to a public institution gradually dropped out of use, and was only revived with the revival of learning in the West in the times of the Renascence. We owe the first idea of a great national museum of science and art to the "New Atlantis" of Lord Bacon, the first scientific museum in this country to Elias Ashmole, who founded the museum which bears his name in 1667 at Oxford. It consisted mainly of the natural history collections made by the Tradescants, and miscellaneous objects of antiquarian interest, which in the course of time swamped the natural history. Now, under the care of Mr. Arthur Evans, reorganized and rearranged, it is taking its place among the educational institutions of the University. It was not until 82 years after the foundation of the Ashmolean that museums were recognized by the Government of this country in the establishment of the British Museum in 1749 by Act of Parliament.

The modern museum is the outcome of the Renascence, and must keep pace with those great accessions to our knowledge of the history of Nature and of Man which distinguish the new from the old learning of to-day. If it cease to grow it is dead, and should be removed. There is no finality in museum work any more than there is finality in the acquisition of knowledge.

The Muses should not be forgotten in museum arrangements, and form, beauty, and symmetry should be studied as well as the outlines of a rigid classification. As an illustration of this I would refer to the groups of birds in the Natural History Museum at South Kensington, or to some of those in the museum at Newcastle. "A thing of beauty is a joy for ever." There is no reason why things beautiful in themselves should be treated so as to repel rather than attract. The element of fit association, too, is one of the important principles. In the case of the temporary exhibition of pictures in the Academy, the fit association of subjects cannot be studied, but there is no reason why in an art gallery the Muses should be scared by a Venus being placed close to local worthies, or a Madonna close to a party of Bacchanals. In museums as in armies the results are largely dependent on the leaders, who leave the impress of their personal character on their commands. The impulse to the new learning given by Ashmole, Hunter, Flower, and by Franks and Newton in this country, by Leidy, Dana, Marsh, and Agassiz in the United States, will last as long as the museums which they founded and organized. In Paris the name of Cuvier is inseparably bound up with the Museum of Natural History in the Jardin des Plantes. In Berlin the Ethnological Museum, and the anatomical collection at the Charité, will keep fresh the memory of Bastian and Virchow in a far distant future when the names of the great political leaders of these times are fading away. It is, therefore, of primary importance to choose good leaders for museum work, and to offer those inducements which will command the services of the best men.

The Old Local Museums in Britain.

When I first began to study the question, some thirty years ago, most of the local collections in this country were in a deplorable state. They consisted largely of miscellaneous objects huddled together with more or less care, and more or less—generally less—named. In one you saw a large plaster cast of a heathen divinity, surrounded by stuffed crocodiles, fossils, and models of Chinese junks, which looked like the offerings of devout worshippers. In another I remember a small glass case containing a fragment of human skull, labelled "human skull," and a piece of oatcake, labelled "oatcake," while underneath was a general label with the inscription, "A piece of human skull very much like a piece of oatcake." In a third wax models were exhibited of a pound weight of veal, pork, and mutton chops, codfish, turnips, parsnips, carrots, and potatoes, which must have cost the values of their originals fifty times over. They had labels explaining how much flesh and fat they would make—theoretically—for we who are either lean or fat know that the personal equation has to do with the actual results. They were as carefully modelled as the most delicate preparations of human anatomy. I quote them merely as illustrations of the misapplication of time, money, and museum space.

In many collections art was not separated from natural history, nor from ethnology, and the eye took in at a glance the picture of a local worthy, a big fossil, a few cups and saucers, a piece of cloth from the South Seas, a model of a machine, and probably also a mummy. These objects would be all very well in their places, but being matter in the wrong place, they were covered by the Palmerstonian definition of rubbish. Such collections as these neither please nor instruct. They have no more right to the name of a museum than a mob has to be called an army. Most of us, I think, are acquainted with this type of collection, which is rapidly becoming extinct with the spread of knowledge. I merely quote them as examples of a state of things from which we have fortunately escaped.

The Place of Museums in the New Learning.

The rapid increase of knowledge makes it more and more necessary for museums to be organized, so as to be in harmony with the swiftly changing conditions. The study of things as well as books is daily growing in importance. The historian, for example, formerly content with written records, now counts the results of archæological discovery among the most valuable and trustworthy of his materials in dealing with the history of the past. The story of Ancient Greece is incomplete if the explorations at Mykenæ and Ilios, in Athens, in the Greek islands, and in the Egyptian cities and tombs be left out of account. To the historian the collections of Schliemann, Flinders Petrie, and others are most precious. Nor are they less precious to him who studies art, or to the ethnologist who studies civilization, or to the naturalist who is interested in the distribution of the various types of mankind, or to the technologist who looks to the evolution of handicrafts. The public mind is beginning to realize the value of well-organized museums for purposes of special research as well as of general culture, and thus they appeal to the interest of the many, while books and a taste for books interest a narrower circle. To contemplate in the British Museum the frieze of the Pantheon is of itself an education in Greek art and in Greek ideas of beauty, and the most unlettered visitor to the Natural History Galleries cannot fail to carry away new ideas about the realm of nature. It is obvious, therefore, that in museums we have an instrument of great educational value, if they be organized to meet the increasing demands of modern investigation.

The Classification of the Museums of To-day.

The museums of to-day fall naturally into four groups. (1) The Art Museum, which includes also antiquities arranged from the art point of view. (2) The Natural History, which illustrates the history of nature in its widest sense, and of man in his physical aspects. (3) The Archæological and Ethnological, which deals with the works of man and his progress in civilization. (4) The Technical, in which objects are arranged in relation to industry. The leading idea of the first is art, of the second nature, of the third civilization, and of the last the conquest of mind over matter.

The Principles of Museum Organization.

These four groups are sharply defined from each other. In practice however it is often necessary to use for the illustration of one what, strictly speaking, belongs to the others. In all such cases, however, the reason of the presence of the alien object must be made obvious, if the general effect of the arrangement is to be preserved. For example, in the Manchester Museum, I found it necessary to complete the history of the Tertiary Period to illustrate the first appearance of man, and to carry on the narrative through the prehistoric and historic divisions down to modern times by a small selected series of specimens, showing the progress of mankind. Were it not for this they would be wholly out of place in a collection of natural history. In like manner our Egyptian mummy has its due place in the National Gallery in Trafalgar Square, its *locus standi* consisting in the fact that it illustrates the art of portrait painting among the Alexandrine Greeks of the first century after Christ.

Next in the point of importance to the leading ideas in museum work comes the question of labelling and illustration. The labels should be clear and distinct, and if possible in English as well as in Latin. The specimens should illustrate the labels quite as much as the labels the specimens. All possible means of illustration should be employed, maps, diagrams, restorations, and the like, so that the main points and relations are clearly brought home to the visitor. In addition to the systematic catalogue of each specimen there should also be a popular guide similar to those of the British Museum. It goes without saying that a collection of books is also necessary.

The kind of museum most desirable in any place depends entirely on the local conditions, and there is no hard and fast scheme applicable to all cases. Nor is the question of great or small to be looked at otherwise than as one of detail. A small well-arranged collection in a school or in a village will do the work which it is intended to do as well as large museums in the metropolis, or in a university, or in a centre of commerce. The principles of success are the same in all: they must be orderly, they must be intelligible, they must as far as possible appeal to the sense of beauty. Under no circumstances must unnamed and unknown specimens be allowed to appear. A ragged recruit may be drilled into a good soldier, but he spoils the parade if he appears out of uniform in the ranks. Nearly all of us who have had to do with museums have sinned in this matter, and it is not for me to cast a stone at my fellow sinners.

The work, however, is only partially done when a museum is properly arranged, labelled, and catalogued on the above lines. To make it intelligible in the best possible way, it is necessary that there should be lectures and demonstrations given in the museum itself, in which some special points should be taken up which interest either the general public or the special worker. In my experience oral instruction with the things before the eyes in the museum, and not away from it in the lecture-room, is the best manner of doing this. As an example of this, I would refer to the demonstrations organized in the British Museum by Prof. Stewart Poole, in which ancient art and civilization were dealt with, and to those which have from time to time been given in the national collection of natural history, under the auspices of Dr. Flower. In this relation the British Museum will be found to be one of the most valuable instruments for spreading knowledge in the University which London will have in the future. In this relation, too, the Geological Museum in Jermyn Street, around which are centred some of the ablest men of the time — De-la-Beche, Murchison, Ramsey, Edward Forbes, Tyndal, Huxley, and many others—has done most valuable service. It is in this direction that museums will influence the general education in this country, and take their natural place in the new learning.

Application of these Principles to the Manchester Museum.

I pass now to the application of the above principles to the Manchester Museum, Owens College. Our experience gained in bringing the old collection into harmony with modern requirements cannot fail to interest those who are now engaged in like work, because it may show not only what is to be copied, but what is to be avoided.

When the task of organization was entrusted to me in 1869, there was a large general collection of natural history, and a large geological collection. The former had been a first-class collection in the second quarter of this century, but had ceased to grow, and therefore had become dead. The second was in good order, and, under the care of its founders, Binny, Ormerod, and others, was properly named. Both, however, were in a most deplorable state so far as relates to fittings, and were simply ignored by the general public, and scarcely used by students. The first step was to sweep out of the way the miscellaneous objects which had no place in a Natural History Museum. The next was to organise what remained into a systematic collection in rooms and cases which were unfit for the purpose. Then followed evening lectures and demonstrations in the old Museum building in Peter Street. Later the teaching collections in Owens College were added, and the Museum began to revive and grow, slowly but steadily, as the connection with the College grew closer, till, in 1874, it was transferred to temporary quarters in the attics and basement of the Owens College. It continued to grow in spite of the removal and of the inadequate cases, and the interest of the public was maintained very largely by the system of Saturday afternoon demonstrations in the only part open to the public—the Geological Museum.

The systematic rearrangement in view of the new buildings was taken in hand. The minerals were arranged, labelled, and catalogued, Dana's "Hand-book of Mineralogy" offering a ready-made catalogue. To meet the mining interests of Manchester special groups of the minerals found in association were organized to illustrate the minerals of Derbyshire, the Lake District, Cheshire, the diamond mines, the apatite mines, and the like.

For the special ends of the geological teaching, the rock specimens were also arranged, and special groups were formed to illustrate their association—such as the products of Vesuvius, and of the volcanoes of Auvergne—and to illustrate the destruction of rocks by natural causes. Then naturally followed the classification of the fossils to show the sequence of events in the geological record. In this the Carboniferous flora and fauna naturally took a prominent place, because of the vast importance of the coal-fields to this district. The arrival, too, of the existing higher Mammalia, including man, on the earth, took a prominent place in the Tertiary collections, and formed the leading idea in the Tertiary chapter of a history of the earth, while the story of the earth was fitly closed by a series of groups illustrating the evolution of human culture and the prehistoric and historic periods. The general principle of classification throughout the whole geological series, or, in other words, the historical method, was that of *time*. Next the zoological collections were arranged, as far as the changing classification would allow, zoologically, with a special group for the zoology of Great Britain. The botanical collections, which offered exceptional difficulty, are now in hand. In this manner the whole of the collections were arranged for the time when they should find their place in the new buildings, and pass under the care of the professor in each department. A scheme of uniformity was carried out with regard to fittings and mounts also; a definite unit of size, 4″ × 1½″, was decided upon, and all tablets and glass boxes were made either on that or on multiples of that. This unit also ruled the size both of the drawers and of the cases in the new fittings. The system of printed labels in which black ink represents the specific name and the red the name of the group was also devised. In the plans of the new Museum the maximum amount of light, consistent with stability and architectural beauty, was the leading idea, while the laboratories and lecture-room of the whole of the Natural History Department of the College were brought as close as they could be to the Museum. The building itself was designed to suit the organization of the collections. Thus step by step the present Museum was gradually built up, and when the buildings were completed in 1884 the collections were transferred to the quarters which they now occupy, and where they form a centre towards which other collections gravitate.

While the museum has been rapidly growing during the last eight years, the system of museum lectures and addresses to various organizations, mechanics' institutes, schools, and the like has been largely developed. In its present state it is used largely by students of Owens College, and is growing in favour with the general public. In other words it is taking the place it ought to have in the education of this densely populated district. These results, it must be observed, have only been possible through the liberality with which the Museum has been treated both by the public and by Owens College. I look forward with confidence to the time when both will be amply repaid by the impulse it is giving, and will give, to the new learning.

I do not for one moment suppose that a natural history museum of this kind is suitable for all places. The *genius loci* must be, in all places, the genius of the museum. The principles however of success are the same in all, and success can only be achieved in a limited degree if there be no signs of the worship of some of the Muses in the arrangements.

The Work of the Museums Association.

In ending this address, all too long, I fear, for my audience, all too short for my subject, I must add a few words as to our work as a Museum Association. It is twofold. First, we must arouse ourselves to the present situation and note the directions which the intellectual movement of the day is taking. Next, it is our duty to arouse the public to the importance of museum development, and to take care that the claims of museums as instruments of education shall not be ignored in the grants made by public bodies for the good of the commonweal.

ON THE CARBURIZATION OF IRON.

I.

THE conditions under which carbon combines with iron have been closely studied, and the observed phenomena fully discussed. Even now, however, it is doubtful whether true chemical combinations of carbon and iron are formed. It has been alternatively assumed that carbon is with difficulty soluble in iron, and that at low temperatures solution may proceed very slowly. In other words, carbon is not easily dissolved except at high temperatures; and it follows that if highly heated iron fully charged with carbon be cooled, a portion of the carbon must be precipitated in this state, existing simply as foreign matter in the metal, but that, on reheating, it may again enter into solution. Low carbon steels may be regarded as dilute solutions of carbon in iron; pig or cast iron as saturated; and intermediate grades may be termed moderately concentrated solutions.

Against this, however, there is a mass of evidence which deserves attention and cannot be ignored. Percy states that for the full carburization of iron a high temperature is necessary, and further, considering the absolute infusibility of carbon, it seems reasonable to assume that these elements must enter into chemical combination. It is, however, admitted that this compound may have the power of dissolving additional carbon; this explains the copious deposition of carbon in the graphitic form when iron is cooled. Dr. Percy finally concludes that there must be at least one definite compound of carbon and iron, but adds that there seems to be no reason why solution should not occur, as in the case of mercury, which liquefies gold, silver, or copper.

Prof. Roberts Austen also ("On Certain Properties common to Fluids and Metals," Royal Institution, March 26, 1886) speaks of the power which certain solid metals have of even rapidly taking up fluids—clearly cases of solution. Abel claims to have proved the existence of a definite compound of carbon and iron. Prof. Roberts Austen also finds that heated iron combines with pure carbon in the form of diamond dust. The author also has succeeded in directly combining iron fused *in vacuo* with pure sugar charcoal presumably freed from gases by repeated heatings *in vacuo*. Yet it is obvious these instances may all be explained on the theory of solution at elevated temperatures, with the exception of Prof. Abel's, who claims to have isolated a definite carbide of iron from the metal.

Matthieson, as the result of an elaborate research, states that "with few exceptions" most of the known two-metal alloys are solidified solutions of one metal in another. Carbon-iron alloys may be looked upon as solidified solutions of carbon in iron, and the analogy of cast iron with other alloys indicates the non-existence of chemical combination between carbon and iron.

Again, viewing alloys as definite chemical combinations, the facility with which heated iron absorbs certain gases does not admit of easy explanation.

Deville, however, imagines a kind of porosity in the metals, terming it an intermolecular porosity, sufficient to admit of the passage of gas at a low temperature; and supposes it developed by the expansive agency of heat. Graham assumes that the affinity of the gases for iron and platinum is as the attraction admitted to exist between a soluble body and its solvent.

Other metallurgists are of opinion that carbon does not directly combine with iron, attributing their union to the direct action of carbon monoxide gas always present in iron; by the agency of this gas carbon is indirectly transferred to iron; but it would appear that this cannot be maintained, for it has been proved that carbon combines directly with iron one way or the other, *i.e.* by solution or chemical combination.

Whatever may be said of irons containing an excess of carbon, *i.e.* cast iron and very hard steel—which, if one grants that carbon is not very soluble in iron at a low temperature may be termed supersaturated solutions—in the case of low carbon steels there seems some ground for assuming that carbon is merely dissolved in the metal.

Sir L. Bell tells us that, on heating thin sheets of carburized metal or steel piled closely together, the excess of carbon contained in one or more of the sheets is transferred to the others. Wrought iron is carburized in much the same manner by the cementation process, and it is equally possible that heterogeneous iron, *i.e.* iron containing intermixed carbon or graphite, and as a rule not equally diffused, may by continued sufficient heating become practically homogeneous.

It is a well-known fact that the carbon in low carbon steel —for instance, Bessemer steel—exists in at least two different forms; Prof. Ledebur says four. Akerman (Iron and Steel Institute) classifies these as (1) hardening carbon, or the carbon which determines the quality of steel, (2) cement carbon, and also graphite may be present.

The united researches of many workers in this field of research indicate generally that a portion of the total carbon is in intimate union with the metal, and that the more intimately combined or hardening carbon determines the quality of the steel. The carbon incompletely combined (or intermixed carbon) is termed cement carbon, because it occurs in the largest proportion in blister or cement steel.

Does not the above point to a case of solution of carbon, in which the quantity in solution is determined by temperature, just as with other solutions?

Metallurgists, however, can hardly accept the theory of solution without qualification.

Mr. Spencer states that "unhardened steel containing 1·18 per cent. total carbon—of which the colour test indicated ·89 per cent. as combined carbon, and residual carbon or graphite ·29 per cent.—after being hardened, gave only ·58 by colour test, and only traces of graphitic carbon, showing a loss of ·51 per cent. of carbon. A softer steel, containing ·50 total carbon—equalling ·45 per cent. by colour test, ·04 per cent. graphitic carbon—after hardening, only ·21 colour test carbon; graphitic carbon ·00, showing a loss of ·29 per cent. Other analyses were made confirming the above, and establishing the fact that after hardening there is always a proportion of carbon which can neither be determined as graphite or by the colour test, and this proportion is found to increase according to the larger amount of carbon in the metal, and the rapidity with which it was cooled" (Mr. Spencer, Iron and Steel Institute).

The facts above quoted are not apparently in accord with the theory of solution; but there are undoubted allotropic modifications of carbon, and this peculiar form may be one of these, "uncombined," and may be classified with the graphite, or really as merely intermixed foreign matter.

There is the alternative assumption that the missing carbon may exist in some form or combination with the iron, possibly not capable of being registered by the colour test; but as the steel is treated with dilute nitric acid, in which it is completely soluble, with the exception of the graphite, this assumption can hardly be maintained.

Referring to Akerman's assertion that only combined "hardening" carbon determines the physical properties of steel—an assertion with which Mr. Spencer agrees—"The apparent loss of carbon shown by the latter, and which we have determined as intermixed carbon or a form of graphite"—it may well be that the missing carbon is so intimately mixed as to be in a state closely bordering on solution, for it is well known that it is difficult to draw the line between absolute solution and matter finely suspended in a liquid. The latter practically often presents the appearance of a solution scarcely to be distinguished from it. Messrs. Harold Picton and L. E. Linder (Chem. Soc., January 1891) are of opinion that there is a continuous series of grades of solution passing without break from suspension to a crystallizable solution. This seems very probable, and in accordance with our chemical experience.

Graphite, if the author has adequately grasped Prof. Akerman's views, has little or nothing to do with the quality of iron. "Graphite carbon exerts an influence only on iron in so far as it diminishes the continuity of the iron molecules. We often meet with the incorrect statement that the influence of carbon on pig-iron is quite different from its action on steel and malleable iron.

"It is easy to prove to the contrary if we distinguish properly in pig-iron between the combined carbon and that which is only mechanically incorporated as graphite, which ought not to be included in the calculation if we wish to form a judgment on the properties of pig-iron as dependent on its contents of carbon."

As one understands this, the same applies to steel.

So far there can be no difficulty in assuming at least the probability of the solution of carbon in iron, and that the physical qualities of the metal are determined by the quantity of carbon in solution, *i.e.* Akerman's hardening carbon.

The facts, *per contra*, appear mainly to indicate that carbon is merely sparingly soluble in iron at temperatures below its fusion-point.

A more serious objection (previously referred to) is that carbon is practically infusible, more especially in the graphitic form. How this intractable body so readily interpenetrates iron is a problem not easily solved.

The ordinary chemical theory of solution as usually understood does not, however, seem applicable on the whole; but some of the results accruing from the recent development of the gaseous, or rather physical theory of solution, may be made available for this purpose.

The Physical or Gaseous Theory of Solution.

In cases of simple solution the dissolved substance may be regarded as being evenly distributed throughout the solvent. The substance is dissolved by virtue of osmotic pressure, and Van 't Hoff has shown that osmotic pressure in solutions corresponds to gaseous pressure in space.

Further, it appears that both Boyle's and Charles's law holds good, at least for dilute solutions, osmotic being the equivalent for gaseous pressure, which pressure increases for constant volume proportionally to the absolute temperature. It has been, however, objected that Boyle's law is not strictly applicable to "more especially concentrated solutions," but Prof. Orme Masson (NATURE, February 1891), states that these are comparable with the case of gases at high pressures. Again, exceptions are claimed under the law of Avogadro, *i.e.* equal volumes of gases contain equal numbers of molecules under like conditions of temperature and pressure, but as regards compound gases exceptions occur, as also with dilute solutions.

Exceptions can be explained by the theory of dissociation. The analogy between gases and the physical theory of solutions thus seems complete, and Ostwald describes an experiment indicating the existence of free ions in a dilute solution of potassium chloride; other instances might also be quoted.

The author's object, however, is not to discuss the absolute correctness or otherwise of the theory of gaseous solution, which seems pretty well established; but to show that it may be applicable to the solution of carbon in molten, semi-fluid, or even merely heated iron, apart from possible cases of dissociation and chemical combinations. Solution is simply the even distribution of one body in another, or such distribution as that of permanent gaseous matter through space. It may be urged that the theory is not applicable to semi-fluid or merely heated iron. No definite line can, however, be drawn; it is obvious that the different grades of temperature are simply approximations, more or less, to the ideal fluid condition. The law of solution, as above defined, may suffer modifications, but need not in consequence be rejected.

"*Definition of Osmotic Pressure.*[1]

"Osmotic pressure is really a definite force. With suitable apparatus this force can be measured, in centimetres of a mercury column, and Pfeffer has shown that this, the osmotic pressure, is intimately connected with the nature of the dissolved substance.

"The pressure was found to be dependent on, and in proportion to, the concentration of the solution; the pressure at a specified concentration is dependent on the temperature—a rise in temperature corresponds to an increase in pressure.

"This discovery remained unnoticed. In the first instance the facts were only required for the elucidation of certain physiological questions.

"And it was not until 1886 that Van 't Hoff developed a theory of solution based on these phenomena.

"Osmotic pressure is a specific property of the substance in solution, and in this respect resembles gaseous pressure. The analogy between the state of solution and the gaseous state is clearly shown (pp. 115–17). Dissolved substances exert the same pressure in the form of osmotic pressure as they would exert if they were gasified at the same temperature without change of volume.

"All that we know of gases holds good for solutions, substituting osmotic for gaseous pressure.

"Osmotic pressure is, in some instances, very great."

And it seems clear that osmotic pressure is not a mythical, but a real or actual force of considerable power, and one which may be rationally applied to the elucidation of the cause of the carbonization of iron; further, it may even afford a clue to the phenomena observed in the production of other alloys.

As regards the carburization of iron, the physical theory of solution, "founded on the identity of osmotic with gaseous pressure," seems the only one capable of affording a satisfactory explanation of the facility with which carbon combines with iron.

The chemical, or old, theory of solution apparently fails to do this. The same may be said of the assumption that chemical combinations of iron and carbon are formed. Although it must be granted such combinations may exist, yet, in the author's opinion, complete proof is still wanting. It is really difficult to realize, when dealing with stable bodies like iron and carbon, how their union can be thus accomplished.

On the contrary, the application of the law of osmose renders the conception of the transfer of carbon to iron very easy. This force, exerting probably almost illimitable power in nature, seems the only one capable of overcoming the *inertia* of bodies; such, for instance, as that of iron and carbon.

The physical theory of solution has hitherto only presumptively herein been applied to the solution of solids in liquids; and it may be asked, Is it applicable to the case of the solution of solids in solids, such as carbon and iron, when heated?

To this one can reply with confidence that the absolute solid has no existence. Unless we reject the atomic theory, it is evident that no tangible mass of matter can be termed a solid: it is an agglomeration of atoms. Further, accepting the definition of what is termed the atomic volume—*i.e.* the space occupied or kept free from the access of other matter, by the material atom itself, together with its investing sphere of heat—it follows that the atoms must be apart from each other in the so-called solid mass, and the distances between the atoms are probably considerable as compared with the actual volume or size of the atoms themselves. Therefore, there can be no difficulty in conceiving that osmotic pressure plays a part in the case of a mass of matter, "conventionally termed a solid." It is only a question of degree; the quantity of matter dissolved in a given time is simply a function of the temperature applied, and at a low temperature, the effective osmotic pressure in the case of solids seems comparable to that of a liquid evaporating under pressure of its own vapour. Evaporation is retarded, and the analogy may hold good in the case of the conventional solid.

JOHN PARRY.

---

[1] Ostwald, "On Solution."

PHOTOMETRIC OBSERVATIONS OF THE SUN AND SKY.[1]

ATTEMPTS have been made by Clausius and various other mathematicians to calculate the light at different points of the perfectly clear sky, and to compare the light of the whole (or a portion) of the sky with that of the sun. The difficulties of photometric measurement have prevented any of the theories being thoroughly established by experimental verifications.

In the first period of photography, it became a matter of practical importance to have some way of testing roughly the "actinic activity of diffused daylight," in order to obtain a guide for the time of exposure. Very many photographers, in those days when the evils of over-exposure could not be corrected in the printing, must have exposed a scrap of sensitive paper, and thence concluded how many seconds' exposure they would allow.

---

[1] "Photometric Observations of the Sun and Sky," by Wm. Brennand. Proceedings of the Royal Society, vol. 49, n. 288, April 18, 1891, pp. 255–280.

From this point it would be a very easy step to test the "actinometric effect on sensitized paper" ("chemical action" of Roscoe) of different skies, or of the sun at different altitudes. It is not probable that the chemical action is simply proportional to the light; but it would be soon found that the "chemical action" could be much more accurately measured than the light.

Sir Henry Roscoe (partly in junction with Bunsen and with Thorpe) made many investigations and various publications between 1859-70 on the chemical action of the sun and sky as measured by its effect in darkening photographically sensitized paper. Roscoe delivered the Bakerian Lecture in 1865, "On a Method of Meteorological Registration of the Chemical Action of Total Daylight."

Throughout his investigations Roscoe pursued a direct method of experiment: he elaborately investigated a method for obtaining always paper of standard sensibility; he devised a plan for obtaining a light of standard intensity; he then exposed a piece of the paper to the action of the sky, or of sun and sky, or of a portion of the sky, and compared the effect produced in a given number of seconds with that produced in the same paper in the same number of seconds by his standard light. Roscoe also, by a laborious method, verified his fundamental asumption that light of intensity 50 acting for 1 second has the same effect as light of intensity 1 acting for 50 seconds.

Roscoe took half-hourly readings at Manchester, and thence gave the (comparative) actinic effects of the sky at different seasons of the year. Also he compared the chemical intensity of total daylight at Kew and Para, and investigated the relation between the sun's altitude and the chemical intensity of total daylight in a cloudless sky. By total daylight Roscoe meant the chemical action produced by the sun and whole sky together on a piece of paper exposed horizontally.

Roscoe found that his readings were enormously affected by the cloud-haze or invisible vapour in the air in England; he got his results, as to comparison of the chemical intensity at different seasons of the year, and at different altitudes of the sun, by assuming that in the average of a large number of observations, the effects of cloud, &c., would be self-destructive.

Roscoe found that the "chemical effect" of the sun depended only on his altitude (in a cloudless sky), being the same at Para and at Kew. He got very anomalous results as to the effects in spring and autumn in England, probably because the effects of cloudiness were not self-destructive in his series of observations. He arrived, by "averaging" the cloud irregularities, at the law that "the relation between the sun's altitude and the chemical intensity of total daylight is graphically represented by a right line" (a result only a rough first approximation to the truth). Roscoe obtained small result in comparing the chemical action at different points of the same sky, partly because he could make no experiments in person on a tropical clear sky, partly because to note these differences requires superior instruments to the direct experiment method alone tried by Roscoe.

Mr. W. Brennand was engaged at Dacca in observations, parallel to those of Roscoe, and nearly contemporaneous, 1861-66. Brennand was quite unaware of Roscoe's experiments. Being an amateur photographer, and his own photographic chemist, he was first led to devise an instrument for testing the chemical action of sun and sky, in order to obtain guidance for the number of seconds to expose a photographic plate. He was soon led on to investigate the effect of the sun at different altitudes, the effect of the sky for different altitudes of the sun, and finally the law of distribution of the "chemical action" in a perfectly cloudless sky.

Brennand's procedure in experiment differed fundamentally rom Roscoe's in two points:—

(1) Brennand only attempted observation in the cold weather at Dacca when he had a complete horizon of clear sky. He was thus enabled to carry his investigations into the laws of chemical action in a cloudless sky much farther than Roscoe, 90 per cent. (at least) of whose observations were obscured by cloud irregularities that could not be allowed for.

(2) Instead of Roscoe's direct method of observation, Brennand was early led to devise an instrument (the water-motion actinometer (see NATURE, January 8, 1891, p. 237), by the aid of which he was independent both of the standard light and standard paper attained by Roscoe with so great labour. The sun himself was, in fact, Brennand's standard light, and the darkening of each paper was read as a ratio; for instance, if an exposure of 10 seconds to sun and sky produced the same tint in the paper that was produced by the sun alone in 17 seconds, then the effect of the sun alone was reckoned $\frac{10}{17}$ of the sun and sky together. It is clear that *any* uniform paper should give such ratios the same, though the actual shades produced would be different in different papers. All the papers made by Brennand himself were found "uniform," *i.e.* to within the limits of variation (say, 2 per cent.) within which the darkened paper can be read, *i.e.* the shades can be matched. Any good photographic paper is found uniform enough for the purpose; but some of the ordinary photographic papers tried lately in England have been found not good enough; the nature of the irregularities introduced by imperfect paper is such as to suggest very soon their cause.

It is to be noticed that all that can be observed is a ratio: the observations in Roscoe's direct process are not absolute. In that process there is a standard unit, viz. the blackness produced in the standard paper by the standard light action at the unit of distance for n seconds. Any other light that produces this blackness has the numerical value $\frac{x}{n}$ in Roscoe's unit. There is little doubt but that Roscoe got his standard light and standard paper, each time he recovered them, correctly within the percentage of error involved in the reading. He would be certain to have prepared his salts of exactly the proper strength; but there is an element of uncertainty in the degree in which papers apparently of similar texture and in a similar state of dryness, &c., take up salts. This element of uncertainty is avoided by Brennand's method, which is far more absolute than Roscoe's.

The water-motion actinometer gave Brennand, for each observation, a shaded strip darkened gradually from 0 to 8 (or to 16) seconds. He could note on this the point at which a particular unit of darkening was produced, and the inverse of this time gave him a measure of the ratio of the observed "chemical action" to that which had produced the unit darkening.

This, of course, involved the assumption that light of intensity 50 acting for 1 second has the same effect as light of intensity 1 acting for 50 seconds. This Brennand thought might be assumed; but he proved it in the following very simple manner.

A slip of sensitized paper is formed into a ring (a short cylinder) and placed round a light (the wick of a candle was used, but any light would do, irregular or not) excentrically. After a certain time the slip is examined and found to be shaded gradually from the farthest to the nearest point, the effect at each point varying inversely as the square of the distance.

Thus if A be the source of light, O the centre of the ring, and if we have $OB = a$, $OA = b$, $POB = \theta$, we shall have the chemical effect at any point P of the slip vary as

$$\frac{1}{R^2} = \frac{1}{AP^2} = \frac{1}{a^2 + b^2 - 2ab\cos\theta}.$$

In a particular experiment Brennand took $a = 1\cdot4$ inch, $b = \cdot4$ inch.

$$\cos^2\frac{\theta}{2} = \frac{3\cdot24 - R^2}{2\cdot24}.$$

Taking the unit of intensity that at the distance 1 inch from the wick, and calculating the values of θ for values of the intensity 1, ·75, ·5, and ·3, we have $\theta = 0, 20^\circ\ 10', 78^\circ\ 34'$, and $141^\circ\ 48'$ respectively. The lengths of arc corresponding to these are found to be ·49 inch, 1·92 inch, and 3·45 inches respectively. These lengths can be marked off on the slip. Another slip can then be darkened in the water-motion actinometer, by any light; a unit can be marked on this slip at the point where the shade corresponds with that at the unit in the ring slip; it then can be seen whether the intensity of shade at the distance ·49 on the ring slip agrees with that at three-fourths the time for unit on the actinometer slip; and similarly for the other calculated values. This experiment verifies the law assumed, and moreover affords a check on the paper employed, and on the closeness with which tints can be matched.

Another important means of verification was employed by Brennand, which Roscoe does not appear to have availed himself of. Calling the effect of the sky alone in darkening paper B, and the effect of the sun and sky together A, Roscoe observed A and observed B, and then calculated the effect of the sun alone as A − B. Brennand did this; but also observed the sun alone by the simple device of a vertical slit in a shutter, and was thus able to check the accuracy of his method and of his work.

Having thus established the trustworthiness of his *modus* *operandi*, Brennand, with his water-motion actinometer, drew up, by an ample series of observations extended over several years, the Table B given in NATURE (January 8, 1891, p. 237). The numbers in this table are ratios, and they may be all multiplied by any number without any real alteration in the table. The unit of chemical action originally started with was the blackness produced by 100 grains of a candle burnt at the unit of distance; and this is the unit which underlies Table B. Brennand early found, as Roscoe found, that the sun has always the same effect at the same altitude in a perfectly clear sky. Hence, in all the later observations the unit was recovered from the sun.

Thus, to take a series of observations, with the water-motion actinometer, with strips of an unknown (but uniform) paper: first, a strip is placed in the instrument, the sun alone being admitted by the vertical slit, and the sliding shutter is run up; we thus get a gradually tinted slip beside the gauge marked in seconds. The altitude of the sun is noted; suppose it 30°; the number in Table B for this altitude is 0·1070, *i.e.* the number of seconds which produces unit darkening by sun alone at this altitude is $\frac{1}{0\cdot107}$ seconds $= 9\frac{1}{3}$ seconds. Then on the sun strip a mark is made opposite the $9\frac{1}{3}$ seconds graduation on the gauge; this is the unit blackness for the paper, and any subsequent strip exposed is "read" by marking the point on it which has the same blackness.

This method of recovering the unit is not sufficient to determine, for instance, whether the sky in England on a certain morning was really clear, *i.e.* as truly clear as the Dacca cold-weather sky. To determine this particular point, Brennand lately in England burnt 100 grains of a candle (as near as he could get) similar in composition to his Dacca candle, and the result shows conclusively, by the exact accord of several observations lately made near Taunton with corresponding old observations at Dacca, that in this case the two candles must have produced equal effects. But it is obvious that the candle could only be trusted by these results. The experiments made with the candle were not made to recover the Dacca unit, but to test the candle. The exact agreement in the several results raises the very strongest presumption that the Taunton candle was equal to the Dacca candle. It is, however, possible that the Taunton sky varied for the several observations in exact ratio with a variation in the Taunton candle; and it can only be said that Brennand's observations on this particular point, so far as they go, support Roscoe's result that the chemical action of the sun is the same at the same altitude in a perfectly clear sky, always and everywhere.

When the chemical action of the sky (or of some portion of it) on a piece of flat paper is observed, what is measured is the integral of the resolved effects of each sky element. Thus if, as in Roscoe's experiments, the piece of sensitized paper is exposed horizontally, and the effect of the whole sky (the sun being stopped off) is taken, we have the total effect of a ring of the sky distant θ from the zenith to be multiplied by cos θ, and then the effect of all such rings from the zenith to the horizon to be summed. This view of the resultant action suggested to Brennand the more original branch of his investigations. He was early led to suspect that the chemical action of the sky varied in different parts of it. He devised an instrument, which he calls the mitrailleuse actinometer, by which he was enabled to prove that the chemical action of the sky is a minimum in the great circle distant 90° from the sun; for an altitude α of the sun this minimum he calls i_α. Brennand then further proves that the chemical action (at the same time) at any other point of the sky distant θ from the sun is then i_α cosec θ.

Having established these important laws, Brennand is able, by mathematical process, having i_α given him, to calculate the total effect of any defined portion of the sky on a plane of sensitized paper exposed at any given angle. He was thus enabled to compare Roscoe's readings of total diffused daylight on paper exposed horizontally with his own Dacca readings on paper exposed perpendicularly to the direction of the sun.

These investigations led Brennand to a theoretic value for the duration of twilight, and to the devising a new instrument, the "octant actinometer," by which the fundamental constant i_α can be observed directly.

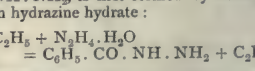
This "octant" actinometer observes one-eighth of the heavens, cut out by three planes at right angles to each other, placed so that the line OS, the intersection of two of the planes, passes through the sun. Owing to the cloudy skies of Taunton, Brennand (who experiments only with a clear sky) had been able very imperfectly to test this instrument at the time his paper was read to the Royal Society. He has since found that this "octant" may be turned in any way round OS (above the horizon, of course) without altering the reading on either of the three planes of the octant. This "octant," therefore, only requires one-fourth of the visible hemisphere round the zenith to be clear, for a good observation. What is more important, it enables the observer, when the sky is clear, and the sun's altitude from 30° to 60°, to take an observation of a part of the sky entirely 30° from the horizon; so that the uncertainty arising from haze near the horizon (which could not before be allowed for) may by this capital instrument be avoided, and i_α obtained without any integrations or calculations beyond division by a number.

In the whole of these later developments, Brennand's work is entirely original. Sir Henry Roscoe, following a somewhat different course of inquiry, has made experiments on the chemical action of the sun and sky at different levels above the sea; and on the total effect during different months or seasons of the English sky with all its cloud, fog, and smoke; which last is an important practical measure of the climate in its influence on vegetation, and perhaps on human health.

The researches of Roscoe and Brennand have thus, though overlapping at particular points, extended mainly in different directions. Brennand, in the ground covered by both, puts forward far the more accurate determinations; his table (B) given in NATURE, January 8, 1891, p. 237, professes to be of the same character and value as a table of the constants of refraction,—Brennand has had half a century's experience with the chemistry of photographic paper, and is an excellent mathematician of the old school. Moreover, the three leading actinometric instruments he has devised, the water-motion, the mitrailleuse, and the octant, show him to be possessed of much resource in devising instruments of research.

INORGANIC SYNTHESIS OF AZOIMIDE, N_3H.

A METHOD of synthesizing this interesting compound of nitrogen and hydrogen, by means of a simple reaction involving only purely inorganic substances, has been discovered by Prof. Wislicenus, and is described by him in a communication to the current number (No. 12) of the *Berichte* of the German Chemical Society. The reactions by which azoimide has hitherto been obtained have all been of an organic nature, and more or less complicated. The mode of preparation described by its original discoverer, Prof. Curtius, in reality depends upon a very simple reaction, that of nitrous acid upon hydrazine, N_2H_4, the other hydride of nitrogen whose preparation we also owe to Prof. Curtius,



$$\begin{array}{l}NH_2\\ \mid\\ NH_2\end{array} + HNO_2 = N_3H + 2H_2O.$$

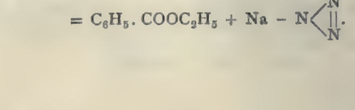
Hydrazine, however, has only yet been prepared from its organic derivatives, and moreover it has not been found practicable to actually convert free hydrazine itself by means of nitrous acid into azoimide, only certain organic derivatives being acted upon by nitrous acid with production of azoimide. The perfected mode of preparation described by Prof. Curtius at the close of last year is very briefly as follows. Benzoyl hydrazine, $C_6H_5 . CO . NH . NH_2$, is first formed by reacting with ethyl benzoate upon hydrazine hydrate:

$$C_6H_5 . COOC_2H_5 + N_2H_4 . H_2O$$
$$= C_6H_5 . CO . NH . NH_2 + C_2H_5OH + H_2O.$$

The benzoyl hydrazine is then converted by means of nitrous acid, obtained from a mixture of glacial acetic acid and sodium nitrite, into the benzoyl derivative of azoimide:

$$C_6H_5 . CO . NH . NH_2 + HNO_2 = C_6H_5 . CO . N\Big\langle\begin{array}{c}N\\ \|\\ N\end{array} + 2H_2O.$$

From benzoyl azoimide the sodium salt of azoimide is next formed by treatment with sodium ethylate:—



$$C_6H_5 . CO . N\Big\langle\begin{array}{c}N\\ \|\\ N\end{array} + C_2H_5ONa$$
$$= C_6H_5 . COOC_2H_5 + Na - N\Big\langle\begin{array}{c}N\\ \|\\ N\end{array}.$$

Free azoimide is finally obtained by distilling the crystals of the sodium salt with dilute sulphuric acid, and repeatedly re-distilling over fused calcium chloride the hydrated liquid which first passes over.

As an alternative method which has some advantages as regards facility of manipulation, Prof. Curtius employs the hippuryl derivative of hydrazine instead of the benzoyl compound The product of the action of nitrous acid upon this compound is a substance which can be readily isolated in crystals, and if these crystals are dissolved in dilute caustic soda, the solution at once yields azoimide upon distillation with dilute sulphuric acid.

Before describing the inorganic synthesis of Prof. Wislicenus, it may be mentioned that a still simpler organic synthesis of azoimide from the long known diazobenzene imide, $C_6H_5N_3$, has been achieved by Drs. Noelting and Grandmougin. Although diazobenzene imide itself is too stable a substance to yield azoimide directly by simple saponification with soda, these chemists found that its dinitro derivative yielded directly to the attack of an alcoholic solution of potash, the potassium salt of azoimide being formed, which of course gave free azoimide upon distillation with dilute sulphuric acid.

The inorganic synthesis of azoimide now achieved by Prof. Wislicenus depends upon the interaction of ammonia gas and nitrous oxide in the presence of heated metallic sodium. Ammonia and nitrous oxide do not act directly upon each other, not even when a mixture of the two gases is passed over caustic bases—soda-lime for instance. But they react readily in presence of metallic sodium. The explanation of this lies in the fact that the sodium amide discovered by Gay Lussac and Thenard is first formed, and this compound reacts with the nitrous oxide with production of the sodium salt of azoimide:—

$$NaNH_2 + N_2O = NaN_3 + H_2O.$$

The water produced at the same time reacts with one-half of the sodamide, forming caustic soda and liberating ammonia gas:—

$$NaNH_2 + H_2O = NaOH + NH_3.$$

Hence the complete reaction may be expressed by the equation—

$$2NaNH_2 + N_2O = NaN_3 + NaOH + NH_3.$$

As the sodium salt is less explosive than most of the other salts of azoimide, requiring a higher temperature and not being sensitive to percussion, the experiment is not dangerous if proper care is exercised, and even if local explosions do occur they have not yet been observed to shatter the glass tube. Unfortunately glass is somewhat strongly attacked during the reaction, but if iron tubes are employed the reaction is not so completely under control.

In actually conducting the experiment, metallic sodium, in pieces not exceeding half a gram in weight, is placed in a series of large porcelain boats, which are then laid in a glass combustion tube, from which the air is subsequently displaced by means of a current of ammonia gas. The tube is heated carefully in a combustion furnace, when the sodium fuses and gradually passes into sodamide. When all the metal has been thus changed, the stream of ammonia is replaced by one of dry nitrous oxide. The temperature should now be lowered to between 150° and 250°, and for this purpose Prof. Wislicenus surrounds it by an iron explosion chamber, which forms a capital air-bath, the temperature of which can be regulated by observing a thermometer or thermometers inserted in it. The sodamide now slowly increases in bulk and becomes converted into the sodium salt of azoimide. As soon as ammonia ceases to be carried away in the stream of issuing nitrous oxide the reaction is completed. Upon cooling the sodium salt is found as a porous pumice-like substance, much distended by the escaping ammonia.

The sodium salt of azoimide is also formed when ammonia and nitrous oxide gases are simultaneously passed over melted sodium; the yield, however, is not so large, and there is danger of the sodium inflaming in the nitrous oxide.

The fact that the sodium compound obtained is the sodium salt of azoimide has been proved both by direct analysis (a determination of nitrogen yielding close upon the theoretical amount) and by its properties. The product of the reaction on being removed from the combustion tube was thrown into water, and the filtered solution distilled with dilute sulphuric acid. The distillate possessed the intolerable odour characteristic of azoimide, and behaved exactly like a solution of that substance in water. It gave precipitates with nitrates of silver, mercurous mercury and lead, which when separated and dried were found to possess all the properties of the silver, mercury, and lead salts of azoimide respectively. The fact that these salts were those of azoimide was indeed sufficiently apparent from their violently explosive nature, and the characteristic flames which were produced during their explosion. Moreover, gold dust was rapidly dissolved with production of the red solution described by Prof. Curtius.

A quantity of the silver salt was subjected to analysis, and was found to contain 71·7 per cent. of silver, the amount calculated for AgN_3, being 71·8.

Instead of sodium, either potassium or zinc may be employed. Potassium answers almost as well as sodium, forming first an amide when heated in a current of ammonia, which is subsequently converted by nitrous oxide into the potassium salt of azoimide. Zinc likewise behaves in a similar manner, but the yield of the zinc salt of azoimide, ZnN_6, is not so good as in the cases of sodium and potassium. To a greater or less extent, therefore, it would appear that metallic amides when heated in a current of nitrous oxide are generally converted into salts of azoimide. The alkali metals, however, appear to be best suited for practical use.

A. E. TUTTON.

THE REPORTED VOLCANIC ERUPTION AT GREAT SANGIR.

ACCORDING to a Reuter's telegram from Sydney, despatched on July 17, the vessel *Catterthun*, belonging to the Eastern and Australasian Steamship Company, which had arrived at Sydney from China, brought a report of a terrible disaster in the vicinity of the Philippine Islands. She called on her voyage at one of the chief ports of the island of Timor, where rumours had been received according to which the island of Sangir, situated between Celebes and Mindanao, had been destroyed by a volcanic eruption. The whole population, numbering 12,000, was reported to have perished. The captain of the *Catterthun* stated that on the voyage his vessel passed through some miles of volcanic *débris*.

We may not for some time receive further details as to the real extent of the disaster reported by the captain of the *Catterthun*, but in the meantime the following account, by Mr. Sydney J. Hickson, author of "A Naturalist in North Celebes," of the island and of the history of its volcanic energy—which appeared in the *Times* of Tuesday—will be read with interest:—

> Sangir, or "Great Sangir," as it is more frequently called by the natives of the Archipelago, is the largest of a chain of volcanic islands that connects the northern peninsula of Celebes with the southern point of the island of Mindanao. The islands, rising abruptly from the floor of the very deep Celebes sea—a depth of over 2,000 fathoms was found by Her Majesty's ship *Challenger* quite close to Great Sangir—are very mountainous and covered by dense tropical forests.
>
> The islands Ruang and Siauw are both little more than volcanoes standing in the sea, but Sangir is a large island 25 miles long by about 15 miles broad, with undulating hills and valleys occupying its southern half, and the great Awu volcano and its slopes the greater part of its northern half.
>
> When I visited the islands in November, 1885, the Ruang and the Awu were quiet, but the Siauw was sending out dense volumes of smoke that varied little in intensity from day to day.
>
> From the accounts I received from the natives and from the records of the islands in the Dutch books of travel, it seems that the Siauw volcano has never been very violently active, but both the Ruang and the Awu have a history full of most terrible and heart-rending episodes. Of the Ruang I need not say much. The last serious eruption occurred in 1871, when at least 400 persons lost their lives either by the sudden rise of the sea water that accompanied the eruption, or by the showers of stones and ash. Of the Awu volcano we find recorded in Valentijn's "Oud en Nieuw Oost Indien" that a most terrible eruption occurred which lasted from the 10th to the 16th of December, 1711. Sjamsialam and his son, the Princess Lorolabo and her daughter Sarabanong, and over 2000 people of the kingdom of Kandahar were killed. On March 2, 1856, there was another fearful eruption, which lasted until March 17, and destroyed nearly 3000 human lives. The streams of boiling water and of steam which poured down the mountain slopes rather than the flow of lava caused the enormous mortality of this second eruption. After the eruption of 1711 it seems that a large lake of water was formed in the crater, and a certain privileged class of Sangirese were allowed by the gods to visit this lake every three or four months to test the water with their rice. If

the water was hot enough to cook their rice they took it for a sign that an eruption would shortly follow. The great eruption came in 1856. The waters of the lake began to boil, burst their banks, and flowed down the sides of the mountain towards Tabukan and Taruna, causing immense destruction of human lives and property.

Concerning the present eruption we learn very little at present, but it seems to me very improbable that the whole island has been destroyed, and, from the sparseness of the population on the slopes of the Awu, it is also very improbable that so many as 12,000 persons have lost their lives.

The population consists of one Dutch Controlleur, who may possibly be married, some three or four German missionaries with their wives and children, one or two European traders, a few Chinamen, and the remainder Sangirese Malays. The island is governed by five native Rajahs, who are advised by the resident Dutch Controlleur. For many years there has been no war or other disturbance, but the island, notwithstanding the richness of its soil, is not in a very prosperous condition. The only produce of any importance is copra, but some good ebony and other timber is found in the forests that cover the islands.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, July 11.—M. d'Abbadie in the chair.—On a slight additive correction which may have to be applied to the heights of water indicated by sea-gauges when the swelling or choppy agitation of the sea attains a great intensity; case of a swell, by M. J. Boussinesq. From theoretical considerations and practical experiments it appears that a tide-gauge exposed in a lateral basin will not give correct indications of level for a choppy sea, but that it will register a lower level than it would if the water were at rest. For a wave 1 metre high the difference may amount to 1 cm.—On the determination of the density of gases, by MM. Henri Moissan and Henri Gautier. This is achieved by a new method, which makes it possible to determine the density within one or even one-half per cent. from a volume of 100 cc. of the gas. The principle is analogous to that adopted by Dumas in his researches on vapour-densities, and consists in measuring the difference between the weight of a known volume of the gas and an equal volume of air at the same temperature and pressure. If this difference in grammes be denoted by p, and if v denote the volume of the gas or air at temperature t° and pressure H, the density is given by the equation

$$p = v \times 0{\cdot}001293\,(x-1) \times \frac{H}{760} \times \frac{1}{1+0{\cdot}00367t}.$$

The apparatus consists of a glass cylinder of about 90 cc. capacity connected at its lower end with a glass tube leading through an india-rubber tube to a movable flask filled with mercury, by means of which the pressure inside the measuring cylinder can be regulated. The latter is surmounted at its upper end by a weighing bulb separated by a three-way cock, by which communication can be established with a fine bent tube. In the experiment, the bulb is first exhausted, then filled with dry air and again exhausted, this being repeated about ten times. It is then shut off, and the fine tube and the measuring cylinder are filled with mercury by lifting the reservoir. The capillary tube can now be used as a pipette, and the gas is drawn into the cylinder and allowed to assume a constant temperature during the night at the pressure of the atmosphere. The bulb is then exhausted and placed in communication with the cylinder, and all the gas is driven into the bulb by raising the mercury flask. The bulb is then carefully removed, and dry air is allowed to enter so as to bring the pressure nearly up to that of the atmosphere. Lastly, the bulb is placed on the balance; the weight which has to be added or removed to obtain equilibrium represents p, which, substituted in the above equation, gives the density. The specimen of gas operated upon can be subsequently used for other experiments.—On the order of appearance of the first vessels in the flowers of some *Lactucæ*, by M. A. Trécul.—On the effects of cold and drought on this year's harvests, and the means by which it has been attempted to combat the evil, by M. Chambrelent.—On the alcoylcyanocamphors and the benzine-azocamphocarbonic ethers, by M. A. Haller.—On the *Libytherium maurusium*, a great Ruminant of the plaisancian pliocene formation of Algiers, by M. A. Pomel.—Measurement of the absolute intensity of gravity at Breteuil (International Office of Weights and Measures), by M. G. Defforges. This was carried out by means of two reversible pendulums constructed by the brothers Brunner, one being 1m., the other 0·5m. long between the knife-edges. The oscillations took place in air and in a vacuum, the latter being continued for 12 to 24, and once for 50 hours. The results were:—

For the length of the seconds pendulum......	0·993952
For g...	9·80991

GROUSE DISEASE AND FOWL ENTERITIS.

The Etiology and Pathology of Grouse Disease and Fowl Enteritis. By E. Klein, M.D., F.R.S. (London: Macmillan and Co. 1892.)

IN this book Dr. Klein has given the results of an important series of researches made by him upon certain diseases in birds. The malady which has specially occupied his attention is that commonly known as the grouse disease. The book will therefore find a large and appreciative circle of non-professional readers. To all interested in the preservation of game it may be commended as furnishing for the first time an adequate and satisfactory explanation of the origin and mode of propagation of the grouse disease. The book is over and above that a valuable contribution to bacteriology. The very excellent illustrations appended enable one to follow the text with great ease. The birds affected are the red grouse (*Lagopus scoticus*) of our moors. The disease, when it breaks out in the spring or summer, is usually of a very virulent type. A fatal epidemic then arises which carries off large numbers of the birds, to the despair of the owners and keepers, who find themselves powerless to cope with the malady. It is to this quickly fatal epidemic that the name of the grouse disease is applied. Though much written about and much discussed, the origin of this disease has hitherto remained undiscovered.

During the last five years numbers of birds, dead or dying from the disease, were sent to Dr. Klein from moors in England and Scotland. The large amount of material furnished has enabled him to make an exhaustive inquiry.

The result is the most noteworthy account yet published of the etiology and pathology of the disease. Dr. Klein has proved that it is an acute infectious malady primarily affecting the lungs and liver of the birds. The symptoms and appearances are those of an acute infectious pneumonia. Dr. Klein has further discovered the *causa causans* of the disease in the shape of a minute unicellular organism, belonging to the class of the bacteria. This microbe has its special seat in the lungs and liver. It is a bacillus, and is found filling and blocking up the capillary blood vessels in the diseased areas of the lungs and liver. The organism can be isolated from the diseased tissues and grown on suitable media outside the body. In this way a series of culture of the bacilli were made on various soils—gelatine, Agar, beef broth, &c. The manner of growth of the microbe in these culture media is very fully described. The growths obtained were always of the same bacterial species. The pure culture of the bacillus subcutaneously inoculated into healthy animals reproduced the symptoms and appearances of the disease. They proved fatal to mice and guinea pigs, and caused in them a congestion of the lungs and liver. No effect was produced on pigeons and fowls. The most virulent cultures of the microbe were those grown in meat broth to which a piece of coagulated white of egg had been added. The most positive results were obtained with the common bunting and yellow-ammer. These birds were inoculated with a minute drop of a meat-broth culture of the microbe. They succumbed within twenty-four hours. The post-mortem appearances were similar to those found in the grouse, viz., a marked congestion of the lungs and liver. The bacilli were found in large numbers in the lungs. From these experiments Dr. Klein was able to conclude that the grouse disease is due to the microbe isolated by him from the diseased organs of the birds. Unfortunately he has not been able to reproduce the disease in large birds, or to utilize healthy grouse for his experiments. In the latter case the difficulty in obtaining living birds and keeping them in captivity prevented this last and most important proof being furnished. The larger birds experimented with (fowls and pigeons) proved unsusceptible.

The infection of the birds seems to take place through the respiratory organs. Dr. Klein furnishes a very striking experiment in support of this view. A yellow-ammer, after being inoculated with the grouse bacillus, was placed in a cage adjoining to one containing six healthy ammers. These six healthy birds acquired the disease and died.

The autumnal disease of the grouse is similar to the spring and summer disease, and both are caused by the same microbe.

The bacilli found in the autumnal disease are, however less virulent than those found in cases during the spring and summer. The buntings and ammers inoculated with the autumn microbe died at a much later period. Mice that had survived inoculation with the autumn microbe did not succumb when inoculated with the more virulent spring microbe. Dr. Klein suggests that cultures of the autumnal microbe might be used as a protective vaccine for the young birds on the moors. It is to be feared that those on whose shoulders this task would fall might prefer the disease to the cure.

The bacillus is easily killed. A temperature of 60° C. completely destroys its life in five minutes. On the other hand, virulent meat broth cultures heated for twenty minutes to 55° C., retained their virulence and yielded normal growths when grown in a fresh soil. This more prolonged heating so near the critical temperature for the bacilli (60° C.) did not, as one would have supposed, produce any retardation in their subsequent growth or any attenuation of the organisms.

Meat broth cultures, in which the bacilli had been destroyed by heat, produced in mice all the symptoms of the disease. This points to the presence in the meat broth of some poisonous chemical product. The matter is referred to very briefly, but we hope Dr. Klein will soon be in a position to tell us more about this interesting and important discovery.

To prevent the spread of the grouse disease the importance of weeding out suspicious birds from the moors is emphasized. The birds killed should be removed and burned.

Dr. Klein describes in the next place a bacillus which he isolated from garden earth. Guineapigs, rabbits, and mice, when inoculated with this organism, developed an œdema of the subcutaneous and muscular tissues. The organism is aerobic, and grows well in the presence of free oxygen, and on the surface of culture media. It is therefore not identical with Koch's bacillus of malignant œdema, which is an anaerobic organism. Though it resembles the bacillus of grouse disease in certain respects, they are not to be regarded as one and the same microbe.

The second part of the book contains an account of a fatal epidemic amongst fowls which broke out at Orpington in Kent. The symptoms and post-mortem appearances led Dr. Klein to designate the disease fowl enteritis, in order to distinguish it from fowl cholera. The bacillus which is the cause of fowl enteritis is not identical with the bacillus of fowl cholera, and Dr. Klein clearly proves this.

Dr. Klein's bacillus is evidently a less virulent organism. In only one case was the disease produced by feeding fowls with the intestinal contents of a diseased fowl. Experiments on other animals gave practically negative results, except in the case of one rabbit. The virulence of the bacilli was lessened by heat. Fowls inoculated with this attenuated virus could not be infected with the disease. Some practical suggestions are given with a view to combating such epidemics.

The concluding chapter of the book contains an interesting account of a disease in young pheasants known as "Cramps."

We have given but a very brief account of Dr. Klein's important investigations. The book will, however, be read by every one interested in the subjects of which it treats, and with great profit. To other workers in the same field it will prove an indispensable work of reference. We have only detected one misprint, on page 53, where "50° Fahr." should no doubt have read 50°C.

We cannot close this notice without a word of praise for the excellent photograms of Mr. Pringle and Mr. Bousfield. A. M.

ELECTRIC LIGHT CABLES.

Electric Light Cables. (London: Whittaker and Co., 1892.)

A DOZEN years ago, when dynamos and lamps, both arc and incandescent, had been pretty well developed, the general public arrived at the conclusion that it was time to commence the work of central station lighting by electricity. It was not until the plans of these proposed works were taken in hand by the consulting engineers that the difficulties in the way of distribution became fully apparent. It was not well known what strength of current could be safely carried through the conductors; and engineers were rather appalled at the cost of the copper required for maintaining uniform pressure over a district, and at the waste of energy in the conductors. Besides these theoretical troubles in the way, engineers were met by the practical difficulty of devising a secure and efficient means of laying conductors under the streets, and ensuring their proper insulation. Until recently, the rules which must be attended to by engineers to enable them to handle these questions were only to be found in scattered pamphlets and Proceedings of societies. Several scientific men dealt independently with the heating of the conductors, and finally Mr. Kennelly published his splendid experimental work on the subject. Other writers went fully into the economical principles which must be followed in order to secure the most uniform distribution at the least cost. When the alternating-current rendered the employment of high pressures both safe and convenient, many of these precautions became less necessary, but new problems arose which are also generally dealt with only in isolated papers. Inventors sprang up, each advocating his own system of laying mains, and an outsider can gain a knowledge of these only by reading the patent specifications, or by inspecting the progress of works. The mechanical details of making joints, insulating, and so forth, are not much dealt with in the literature of the subject.

The book before us is one of the first attempts to collect all the above principles within one binding. The first few chapters deal principally with the heating of conductors and the economical laws of distribution. Well-known writings on the subject are here condensed into convenient compass, and Kennelly's experimental results are given in sufficient detail. Series and parallel systems and their combinations, including the three-wire and five-wire systems, which serve so much to economise copper, are explained, and also the principles involved in the use of transformers with alternating currents. Having thus described the systems available, we have, in Chapter v., a useful account of the cost of cables and conduits, with tables showing the relative cost of different systems when the distribution extends to different distances, showing the advantages of using high pressure for long distances. Chapter vi. gives a number of practical data about different kinds of conductors and the manner of making joints, which, though not exhaustive, will be of use to many. The next chapters deal with the characters of the insulation, including air insulation, lead-covered cables, the various bituminous compounds known as bitite, &c., oil insulation, and, of course, vulcanized india-rubber, about which the author is particularly capable of giving information. The effects of capacity, which has given so much trouble at some central stations, are also alluded to. These chapters are very fairly written, and give as good an account of the various systems of insulation as is likely to be found anywhere, or as we might expect in a volume of this size, which is more a hand-book of the subject than an exhaustive treatise. Some of the principles of testing are then shortly, but very clearly, described; and the principles of house wiring are clearly shown, and safety devices described. Several good chapters come near the end of the book on the practical construction of lines, whether overhead or underground, the latter dealing chiefly with the actual work which has been done in London of late years.

This book is one of the best which could be taken up by the student to give him a general knowledge of what is involved in the comprehensive title—"The Distribution of Electricity." It does not pretend to be a complete manual for the office, containing all the information required by the consulting engineer in dealing with these problems, but the descriptions are clear and generally accurate, and the only criticism which we feel compelled to make is that sometimes, apparently with the desire of preventing the book from being too technical, or requiring too much mental effort to read it, the author has been, perhaps, a little too sketchy, and might with advantage have given some more detailed information on a variety of points. Nevertheless, we consider that this book is a useful addition to electrical literature, and must be of the utmost use to students in showing the difficulties which have to be encountered in designing a plan of central station working. The general reader will also be much interested in learning something more of the meaning of the work which he sees being carried out at present in the streets of many of our towns. Should the book chance to fall into the hands of any members of electric lighting committees of Municipal Corporations, it will do a vast amount of good, by opening their eyes as to the number of problems that have to be considered in their dealings with different contractors, each generally wedded to a special system. It is to be hoped that this book will teach them that, in trying to act as consulting engineers without the special training necessary, they are not serving the best interests of the towns they represent. Altogether, "Electric Light Cables" is a useful addition to the literature of electrical engineering, and the absence of too many technicalities will make it popular with a large class of readers.

OUR BOOK SHELF.

Distribution de l'Electricité. I. "Installations isolées." II. "Usines centrales." Par R. V. Picou, Ingénieur des Arts et Manufactures. (Paris: Gauthier-Villars, 1892.)

THESE two small volumes are portion of a series belonging to "L'Encyclopédie scientifique des Aide-Mémoire," published under the direction of M. Léauté, Member of the Institute. The second volume is the only one which calls for remark. It deals with the methods, well known in England, of distribution of continuous and alternating currents and systems of high and low pressure. The information given concerning the multiphase and rotary current systems is very scanty and quite out of proportion to the other matters treated of. The reader will naturally look for an account of the method employed for the transmission of power from Lauffen to Frankfort, but he will find no information of any practical service. The author, however, gives a short discussion of the difficulties that must be surmounted if arc and incandescent lamps are to be installed on a circuit fed by a triphaser and three wires.

Information is given concerning the working of some of the principal existing central stations, and there is a useful bibliography.

Popular Readings in Science. By John Gall, M.A., LL.B., and David Robertson, M.A., LL.B., B.Sc. (Westminster: Constable and Co., 1892.)

THIS forms the second volume of Constable's Oriental Miscellany of original and selected publications, and is intended to form the basis of a general course of instruction in science, suited to the requirements of the pupils in Indian schools who are preparing for matriculation at the University. The authors lay no claim to originality, but have exercised a judicious choice in the selection of subject matter. The first chapter deals with meteorology, special prominence being given to Mr. Blandford's researches on the climate of India. Then follow chapters on the vegetable kingdom, evolution, both in its biological and chemical aspects, mimicry, the nebular hypothesis, tidal evolution, energy, the spectroscope, molecular forces, and Bacteria. A reference to the meteoritic hypothesis would make the chapter on the nebular theory more complete. The authors have wisely contented themselves with *descriptions* of theories and plain matter-of-fact statements. The book is very readable, but at times somewhat technical. It would, however, be improved by the addition of more diagrams, though it may be that more can safely be left to the imagination of the Oriental than the Western mind. The narrative style which has been adopted by the authors will make the book acceptable to general readers who are anxious to make acquaintance with modern science.

Geometrical Deductions, Book II. By James Blaikie and W. Thomson. (London: Longmans, Green, and Co., 1892.)

THIS treatise is intended to afford a systematic course of training in the art of solving geometrical problems. The basis of the system which the authors have employed is to be thoroughly recommended, being both logical and simple. The book is divided into sections, each of which consists of three parts. In the first a model deduction is fully worked out to illustrate the method of solution; then follow similar deductions with their figures, and occasional hints; while, lastly, the student is left to himself to solve the problems without any such aid. This principle is maintained throughout the entire book, so that a student should be able to obtain a good working knowledge and should also to a great extent be quite rid of a teacher.

The Appendices will also be found very useful, as they contain the enunciations of the propositions in Euclid's second book and of standard theorems and loci, together with a set of miscellaneous deductions covering the range of Euclid's first two books.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

B.A. Procedure.

THE coming meeting of our ancient and venerable institution, the British Association *for the Advancement of Science*, will doubtless be a large one, as the beauties of Edinburgh are sure to tempt many to attend, and may therefore give opportunity for discussion on a subject of fundamental importance—the future well-being of the Association and the means of retaining it as an object of veneration on account of the services which it *is* rendering and not merely on account of those which it *has* rendered.

It is beyond question that there are many who have long been dissatisfied, and who are of opinion that B.A. procedure is not in harmony with the times. Moreover, to speak plainly, many of us feel that the "tripper" element has become too predominant, and that the credit of science will suffer if a large number of persons be permitted, year after year, to make pleasant holiday, "supported by voluntary contributions," under the pretence of advancing science, while the number of true workers whose reputation alone upholds the claim of the Association to public recognition is but small.

In the great majority of instances the reading of papers on technical questions in the sections has become little less than a solemn and dreary farce played to almost bare benches; and it is only in exceptional cases—such as Section A affords—that a small and devoted body of true believers worship at an inner shrine without regard to the general public, and are thus able among themselves to do work of high value to science.

The B.A. should exercise an influence in two directions—it should advance scientific knowledge among scientific workers; and it should aid the general public in understanding and appreciating scientific work, its methods and results. It may effect the former by bringing scientific workers together and giving them due opportunity for the interchange of knowledge and opinions. To secure this end, it is important that *sectional* and *intersectional discussions* should, in future, become *the feature* of the meetings, but to be successful these must be conducted with far greater forethought than heretofore—they must be true discussions and must not consist of a number of short papers written without reference to each other or to any central idea, and there must be no limitation of discussion so long as it is to the point. Probably the best plan will be that sectional committees, specially appointed for the purpose, select subjects, and that on each of these some one open a discussion by means of a carefully-prepared paper, printed and circulated at least a month beforehand, among those likely to take part in the debate. Such discussions should be carefully reported, and the edited report should be subsequently published, those who had taken part in the discussion having full liberty allowed them to give expression to their carefully-considered opinions instead of being required merely to punctuate their sentences in proof. The resolution not to report discussions arrived at last year by the Council is most unfortunate. If it were understood that discussions would be reported, speakers would be far more interested, and would take far more pains in preparing to take part in them than has hitherto been the case. It is, I think, unnecessary to dwell on the value of true discussion among workers in different, but cognate, branches of science.

As regards the public functions of the Association, it is unquestionable that much more might—and should—be done on behalf of those who are interested spectators rather than active workers in science. The evening lectures now delivered are often very brilliant expositions, but, as a rule, they have been "above the heads" of a very large proportion even of the members of the Association who have listened to them. I know many who think with me that a more direct effort should now be made to advance the knowledge of science among the general public at these meetings.

One great reform which *must* be carried out is the general curtailment of the expenses of the meetings, which make it impossible for any but the largest and richest towns to receive the Association. The lavish expenditure on the Reception Room which has been so frequently witnessed of late years should be unnecessary. So long as we can come together and can accomplish our object—the *advancement of science*—we should be satisfied with the most modest accommodation and should even be prepared to submit to some privation. At the German Naturforscher Versammlungen the vast majority cater for themselves, and private hospitality is almost unknown, the social demon, which is so ruthless a destroyer of much of the effectiveness of the B.A. meetings, being kept entirely in the background; and yet, in my opinion, these meetings are at least as enjoyable and fruitful of result as our own B.A. meetings.

Then we want younger presidents, on the average—men who are in their prime as scientific workers.

Of late years our Council has been far too cautious and conservative a body, and a large infusion of a liberal and progressive element is necessary if we are to set our house in order, so that it may suit the times. Many of us think that the Council is not in touch with us as a body—somehow we know of its existence, but its functions are mystic and akin rather to those of the Archives of the Royal Society than to those of an energizing and propulsive organ. In these democratic days, it would be well if each section were to return a member to Council.

HENRY E. ARMSTRONG.

The Position of 4π in Electromagnetic Units.

THERE is, I believe, a growing body of opinion that the present system of electric and magnetic units is inconvenient in practice, by reason of the occurrence of 4π as a factor in the specification of quantities which have no obvious relation with circles or spheres.

It is felt that the number of lines from a pole should be m rather than the present $4\pi m$, that "ampere turns" is better than $4\pi n$C, that the electromotive intensity outside a charged body might be σ instead of $4\pi\sigma$, and similar changes of that sort; see, for instance, Mr. Williams's recent paper to the Physical Society.

Mr. Heaviside, in his articles in the *Electrician* and elsewhere, has strongly emphasized the importance of the change and the simplification that can thereby be made.

In theoretical investigations there seems some probability that the simplified formulæ may come to be adopted—

μ being written instead of $4\pi\mu$, and k instead of $\frac{4\pi}{K}$;

but the question is whether it is or is not too late to incorporate the practical outcome of such a change into the units employed by electrical engineers.

For myself I am impressed with the extreme difficulty of now making any change in the ohm, the volt, &c., even though it be only a numerical change; but in order to find out what practical proposal the supporters of the redistribution of 4π had in their mind, I wrote to Mr. Heaviside to inquire. His reply I enclose; and would merely say further that in all probability the general question of units will come up at Edinburgh for discussion.

OLIVER J. LODGE.

Paignton, Devon, July 18, 1892.

MY DEAR LODGE,—I am glad to hear that the question of rational electrical units will be noticed at Edinburgh—if not thoroughly discussed. It is, in my opinion, a very important question, which must, sooner or later, come to a head and lead to a thoroughgoing reform. Electricity is becoming not only a master science, but also a very practical science. Its units should therefore be settled upon a sound and philosophical basis. I do not refer to practical details, which may be varied from time to time (Acts of Parliament notwithstanding), but to the fundamental principles concerned.

If we were to define the unit area to be the area of a circle of unit diameter, or the unit volume to be the volume of a sphere of unit diameter, we could, on such a basis, construct a consistent system of units. But the area of a rectangle or the volume of a parallelepiped would involve the quantity π, and various derived formulæ would possess the same peculiarity. No one would deny that such a system was an absurdly irrational one.

I maintain that the system of electrical units in present use is founded upon a similar irrationality, which pervades it from top to bottom. How this has happened, and how to cure the evil, I have considered in my papers—first in 1882–83, when, however, I thought it was hopeless to expect a thorough reform; and again in 1891, when I have, in my "Electromagnetic Theory," adopted rational units from the beginning, pointing out their connection with the common irrational units separately, after giving a general outline of electrical theory in terms of the rational.

Now, presuming provisionally that the first and second stages to Salvation (the Awakening and Repentance) have been safely passed through, which is, however, not at all certain at the present time, the question arises, How proceed to the third stage, Reformation? Theoretically this is quite easy, as it merely means working with rational formulæ instead of irrational; and theoretical papers and treatises may, with great advantage, be done in rational formulæ at once, and irrespective of the reform of the practical units. But taking a far-sighted view of the matter, it is, I think, very desirable that the practical units themselves should be rationalized as speedily as may be. This must involve some temporary inconvenience, the prospect of which, unfortunately, is an encouragement to shirk a duty; as is, likewise, the common feeling of respect for the labours of our predecessors. But the duty we owe to our followers, to lighten their labours permanently, should be paramount. This is the main reason why I attach so much importance to the matter; it is not merely one of abstract scientific interest, but of practical and enduring significance; for the evils of the present system will, if it continue, go on multiplying with every advance in the science and its applications.

Apart from the size of the units of length, mass, and time, and of the dimensions of the electrical quantities, we have the following relations between the rational and irrational units of voltage V, electric current C, resistance R, inductance L, permittance S, electric charge Q, electric force E, magnetic force H, induction B. Let x^2 stand for 4π, and let the suffixes $_r$ and $_i$ mean rational and irrational (or ordinary). Also let the presence of square brackets signify that the "absolute" unit is referred to. Then we have—

$$x = \frac{[E_r]}{[E_i]} = \frac{[V_r]}{[V_i]} = \frac{[H_r]}{[H_i]} = \frac{[B_r]}{[B_i]} = \frac{[C_i]}{[C_r]} = \frac{[Q_i]}{[Q_r]};$$

$$x^2 = \frac{[R_r]}{[R_i]} = \frac{[L_r]}{[L_i]} = \frac{[S_i]}{[S_r]}.$$

The next question is, what multiples of these units we should take to make the practical units. In accordance with your request I give my ideas on the subject, premising, however, that I think there is no finality in things of this sort.

First, if we let the rational practical units be the same multiples of the "absolute" rational units as the present practical units are of *their* absolute progenitors, then we would have (if we adopt the centimetre, gramme, and second, and the convention that $\mu = 1$ in ether)

$$\begin{aligned}
[R_r] \times 10^9 &= \text{new ohm} = x^2 \text{ times old.} \\
[L_r] \times 10^9 &= \text{new mac} = x^2 \quad ,, \quad ,, \\
[S_r] \times 10^{-9} &= \text{new farad} = x^{-2} \quad ,, \quad ,, \\
[C_r] \times 10^{-1} &= \text{new amp} = x^{-1} \quad ,, \quad ,, \\
[V_r] \times 10^8 &= \text{new volt} = x \quad ,, \quad ,, \\
10^7 \text{ ergs} &= \text{new joule} = \text{old joule.} \\
10^7 \text{ ergs per sec} &= \text{new watt} = \text{old watt.}
\end{aligned}$$

I do not, however, think it at all desirable that the new units should follow on the same rules as the old, and consider that the following system is preferable :—

$$\begin{aligned}
[R_r] \times 10^8 &= \text{new ohm} = \frac{x^2}{10} \times \text{old ohm.} \\
[L_r] \times 10^8 &= \text{new mac} = \frac{x^2}{10} \times \text{old mac.} \\
[S_r] \times 10^{-8} &= \text{new farad} = \frac{10}{x^2} \times \text{old farad.} \\
[C_r] \times 1 &= \text{new amp} = \frac{10}{x} \times \text{old amp.} \\
[V_r] \times 10^8 &= \text{new volt} = x \times \text{old volt.} \\
10^8 \text{ ergs} &= \text{new joule} = 10 \times \text{old joule.} \\
10^8 \text{ ergs per sec.} &= \text{new watt} = 10 \times \text{old watt.}
\end{aligned}$$

It will be observed that this set of practical units makes the ohm, mac, amp, volt, and the unit of elastance, or reciprocal of permittance, all larger than the old ones, but not greatly larger, the multiplier varying roughly from $1\frac{1}{4}$ to $3\frac{1}{2}$.

What, however, I attach particular importance to is the use of one power of 10 only, viz. 10^8, in passing from the absolute to the practical units; instead of, as in the common system, no less than four powers, 10^1, 10^7, 10^8, and 10^9. I regard this peculiarity of the common system as a needless and (in my experience) very vexatious complication. In the 10^8 system I have described, this is done away with, and still the practical electrical units keep pace fairly with the old ones. The multiplication of the old joule and watt by 10 is, of course, a necessary accompaniment. I do not see any objection to the change. Though not important, it seems rather an improvement. (But transformations of units are so treacherous, that I should wish the whole of the above to be narrowly scrutinized.)

It is suggested to make 10^9 the multiplier throughout, and the results are :—

$$\begin{aligned}
[R_r] \times 10^9 &= \text{new ohm} = x^2 \times \text{old ohm.} \\
[L_r] \times 10^9 &= \text{new mac} = x^2 \times \text{old mac.} \\
[S_r] \times 10^{-9} &= \text{new farad} = x^{-2} \times \text{old farad.} \\
[C_r] \times 1 &= \text{new amp} = \frac{10}{x} \times \text{old amp.} \\
[V^r] \times 10^9 &= \text{new volt} = 10x \times \text{old volt.} \\
10^9 \text{ ergs} &= \text{new joule} = 10^2 \times \text{old joule.} \\
10^9 \text{ ergs p. sec.} &= \text{new watt} = 10^2 \times \text{old watt.}
\end{aligned}$$

But I think this system makes the ohm inconveniently big, and has some other objections. But I do not want to dogmatize in these matters of detail. Two things I would emphasize :—First, rationalize the units. Next, employ a single multiplier, as, for example, 10^8.

OLIVER HEAVISIDE.

P.S.—Heaven preserve us from dynamics based on the Act of Parliament!

Neutral Point in the Pendulum.

In the theory of the pendulum the position of the neutral point of support is a matter of practical importance, which is, nevertheless, quite disregarded.

Taking a rigid uniform bar as the simplest case, there are four points of support from which its vibrations are equal, the two ends and the two respective centres of oscillation. But there are two symmetric points, situated between either end and the centre of oscillation nearest to that end, from which points of suspension the rate of vibration is most rapid. Hence, when suspended from these points, a change in the position of the point of support produces a minimum difference in the rate of vibration. Or, in practical terms, there is a great advantage in having a small amount of overhead weight above the support, as then, if the support approach the bob (owing to changes in elasticity of the spring, or of the knife edges), and so increase the number of vibrations, it recedes from the top weight, and so diminishes the vibrations to a corresponding amount, and *vice versa*.

This neutral point of support seems to have been overlooked in the main pendulum researches, as it was what had to be avoided rather than sought in the determination of the length, which was then the main interest. Probably some one has already noticed such an elementary property; but it is of so much value in minimizing sources of error that it is worth some attention.

Bromley, Kent. W. M. FLINDERS PETRIE.

Induction and Deduction.

CAN we determine the precise relation between Induction and Deduction? Both are said to be a species of Inference. *Deduction* is, no doubt, Mediate Inference. Is *Induction* Mediate or Immediate Inference? If Immediate it must be of the form :

This X is Y (or these X's are Y's) . . . . . (1)
∴ All X's are Y's . . . . (2)

But such "inference" as this is not illative; (1) can furnish only a suggestion, not by any means a justification, of (2).

Still it is true that if, *e.g.* I have proved that the angles at the base of an isosceles triangle are equal to each other, I henceforth believe and assert unhesitatingly, that *all* isosceles triangles have the angles at the base equal. *How* do I justify such a conclusion of an universal from a particular? In this way, I think :—Every nameable or cogitable object is an identity in diversity—that is, it is itself, it is *something*, and it has a plurality of characteristics. This principle is involved in the assertion of any statement of the form *A is* B, and it seems moreover to be, in itself, evident on reflection. Further (as Bacon surmised), every property (or group of properties) has a "form," some invariable and inevitable coexistent. In other words, there is uniformity of coexistence as well as of causation in nature. In the case of any one isosceles triangle, I have *seen* the connection of interdependence that there is between the characteristics of "having equal sides," and "having the angles at the base equal;" I have perceived it to be self-evident that the one property involves the other. Hence, my whole argument might run thus :—

Every characteristic is invariably accompanied by some other characteristic;

Equality of sides in a triangle is a characteristic;

∴ Equality of sides in a triangle is invariably accompanied by some other characteristic.

Again :—

Equality of angles at the base is a characteristic which is (self-evidently) inseparable from equality of sides in one [this particular] case;

What is inseparable from equality of sides in one case is inseparable in all cases;

∴ Equality of angles at the base is inseparable from equality of sides in all cases—

That is, *all* isosceles triangles have the angles at the base equal.

What we rely on here is Interdependence of characteristics and Uniformity of that interdependence; *i.e.* we rely on a principle of coexistence or coinherence, parallel to Mill's "Law of Causation"; and this is a principle which we find to be a necessary condition of what we accept as strictly self-evident propositions. The assertion with which we conclude in the above generalization, is an assertion of uniformity of interdependence between certain specified characteristics.

Again, if I administer a certain amount of arsenic to a healthy animal, and it dies, and I hence conclude that arsenic is a cause of death, I argue thus:—Since every event (= change of attributes in subjects) has a cause, the death in question had a cause; the only precedent event that was relevant, was the administration of arsenic, therefore the arsenic was in this case the cause of death (this last result is obtained by the Method of Difference—by it we prove cause—*i.e.* interdependence of successive events). But (by the principle of uniformity) if arsenic is on one occasion cause of death, it is always cause of death; therefore arsenic is always a cause of death.

It will be observed that in this second induction, though not in the first, we make use of one of Mill's "Inductive Methods." The function of these Methods is to prove interdependence between phenomena—whether it be an interdependence of concomitance or of causation. In the case of the Method of Difference we proceed on the assumption that if the introduction of A is followed by the appearance of C, or the removal of A by the disappearance of C, then A and C are causally interdependent. In the Method of Agreement we proceed on the assumption that if A is never found without C, A has a connection of interdependence with C.

We do not use, and do not need, these Methods in mathematical generalizations, because there we *see* the interdependence upon which generalization to unknown cases is based; it is this actual apprehension of interdependence that both makes the methods unnecessary and gives mathematical generalizations the peculiar certainty which is generally attributed to them. In the case above cited, for instance, we *see* that equality of angles at the base is self-evidently and necessarily bound up with equality of sides in a triangle. We do *not* see that there is a self-evident interdependence between the obvious properties of arsenic and poisonousness.

A further interesting point is that our power of predicting that one event, A, will be *followed* by another event, C, seems to depend wholly upon *coexistence* of attributes in the subjects concerned. If we have seen one animal dosed with arsenic and subsequently die, and hence conclude that another animal called by the same name, and dosed with an equal amount of arsenic, will die, is not our inference based upon the assumption of a certain constant coinherence of attributes, both in the animal and in the poison—a coinherence of such a kind that when the two subjects are so collocated as to act upon each other, a result similar to that produced in the first case will be produced in the second also? If the properties of this arsenic are different from the other, or if the second animal, though looking like the first, has a different internal constitution, there is no reason why death should result. Hence, laws of succession in events seem to depend upon laws of coexistence of attributes in subjects.

Even those generally unquestioned axioms of logic, the Law of Contradiction and the Law of Excluded Middle, might be appealed to (if it were necessary) in support of the Principle of Interdependence—for the Law of Excluded Middle intimates a thoroughgoing connection (positive or negative) between all nameable things; and the Law of Contradiction asserts a certain definite amount of necessary interdependence of properties in every imaginable case—interdependence, namely, between *the presence of any characteristic* and *the absence of its negative*.

Looking at the whole process of inductive reasoning, it appears to be in the application of the "Methods" that the principles used approach nearest to the character of mere assumptions; and this is so only because of the difficulty of applying the Methods precisely—of being sure, *e.g.* in the case of the arsenic, that the administration of arsenic *was* the only new antecedent relevant to death.

It may just be noticed that in an argument by analogy we rely upon an interdependence which is inferred from the complexity or amount of interdependence already known or supposed.

If the above account of inductive reasoning is accepted, it appears that the connection between Induction and Deduction is very close—in fact, that the one distinctive feature of logical induction is the element of hypothesis or discovery—the supposition of a given connection—from which every Induction must set out.

The Scale for Measurement of Gas Pressures.

I venture to ask you to print the following suggestion. It is one likely enough to have been made before, but I do not remember having met with it.

We generally measure gaseous pressures in millimetres of mercury, and 760 mm. is adopted as the standard pressure. It would certainly be more convenient if we expressed the measurement in degrees, the degree being of such magnitude that the standard pressure were 273°. All calculations involving change of P, T, and V to or from the standard conditions would be simplified in an obvious way. The equation $PV = RT$ would become $V = R$ at standard pressure and temperature. R being the same constant for all gases under all conditions, if V stand for the molecular volume, it would be convenient to remember it as identical with the well-known number expressing the standard volume of a gramme-molecule. 1°P would correspond to about 2·78 mm. or ⅑ inch of mercury.

Luminous Clouds.

Bright luminous clouds were seen here on the night of Sunday the 24th inst., in the north and north-north-east, from 9.35 to 10.35 p.m. As usual they distinctly resembled *cirri*, having some definite upward curls. The actual cirri, which had after sunset been moving rapidly from east-south-east, now appeared dusky against the twilight glow. The filature of the upper or luminous cirri was, as appears to be usual, west and east, while that of the ordinary cirri was east-south-east and west-north-west.

These luminous clouds, although no doubt simply reflecting solar light, generally appear to the casual observer as incandescent or self-luminous.

They were seen from the summit of Ben Nevis all through the night of the 24th–25th, according to the report in the *Times*.

Whirlwinds in the South Indian Ocean.

The following account of whirlwinds met with in the South Indian Ocean at the end of last May, which has been supplied to the Meteorological Office by Messrs. Sandbach, Tinne & Co., of Liverpool, may be of interest to your readers.

Robert H. Scott,
July 22. Secretary, Meteorological Office.

Extract from a Letter received from Capt. S. P. Hearn, Ship "Genista."

"At noon on May 26, lat. 42° 0′ S., long. 99° 0′ E., wind fresh from N.W.—weather very squally with rain, barometer steady at 29·82 in., thermometer 49° since midnight. A very heavy black squall with rain began to rise in the W. Barometer suddenly fell 0·1 in. As the squall neared the ship it arched up in the centre, showing a very bright blue sky at the back of it; the ends of the squall on either side were quite black and thick with rain. On its nearer approach to the ship I saw two immense whirlwinds, just a little on either side of the centre of the arch and coming direct for the ship, the sea under and near the whirls being carried around and up in great volumes. I thought at first they were two waterspouts forming, but I saw no descending column or clouds from above, as is seen when a waterspout is forming; when these whirls came to within two miles of the ship, the squall seemed to part in the centre of the arch—one half passing to the N.E., the other half to the S.E., one whirl following in rear of each part of the squall, and not where the clouds were heaviest. During the time of the separation of the arch we had the wind very unsteady from N.W. to S.W. There was only a fresh breeze with thick rain in that part of the squall that neared the ship; yet the squall was travelling along at a great rate, the whirls keeping in the rear till out of sight. I shortened sail to topsails as soon as I saw the squall rising. After it passed, the weather looked very fine, bright, and clear, but the sky was a windy one, being a very bright blue. By 3 p.m. the wind shifted to W., and barometer had fallen to 29·67 in., thermometer 48°. At 4 p.m. saw another whirl passing along to windward in the rear of a squall, the clouds above it being twined and twisted every way. During the whole night we had very heavy squalls, sometimes following one another very quick, with little wind between—direction W.S.W. At daylight the weather was much finer. After that, to lat. 40° 22′ S., long. 125° E., I had very peculiar weather. Wind from N.W. to S. and back again, from a light breeze to a moderate gale, barometer never rising higher than 29·90 in., or falling below 29·66 in.

The Cause of the Great Fire at St. John's.

A FEW days ago you inserted a letter calling attention to the large number of fatal accidents occurring every year caused by the upsetting of paraffin lamps, the great majority of which could easily be prevented if the use of automatic extinguishers were made compulsory.

Now we are startled by the report of the huge conflagration at St. John's, which, in addition to having caused terrible and widespread suffering, has resulted in the loss of a large amount of property, valued at many millions of dollars.

Amongst the principal sufferers by this great fire are some of the leading English insurance companies, and various estimates have been published of the amounts which they will lose by this great fire. *The Policy Holder*, an insurance journal, in its last issue, mentions the following figures :—

	£		£
Phœnix	120,000	to	140,000
Royal	80,000	to	100,000
Liverpool, London, and Globe	50,000	to	70,000
London and Lancashire ...	50,000	to	60,000
Commercial Union	40,000	to	50,000
North British and Mercantile	50,000	to	60,000
Northern	40,000	to	50,000
Manchester	8,000	to	11,000
Lancashire	5,000	to	7,000
Norwich Union	7,000	to	10,000

Also the "General," said to be £30,000, and the "Lion" for a comparatively large sum, making in the aggregate a loss for English insurance companies alone of over £500,000 sterling.

The same journal explains how this great fire was brought about :—

"It is worthy of note that, like the Chicago fire, this conflagration was caused by the upsetting of an oil lamp in a stable. Fire business was already this year going badly enough, and there now seems little reason to doubt that to the companies as a whole 1892 will prove a disastrous year and a dead loss."

The Mayor of Manchester (Alderman Bosdin Leech), in presiding yesterday at a meeting of citizens called for the purpose of raising a fund in aid of the sufferers by this great catastrophe, stated—

"Since the fire of forty or fifty years ago many substantial public and private buildings had been erected, all of which have been destroyed. On one side, at any rate, a thriving town had been reduced to a heap of ashes, and about 10,000 people had been rendered homeless, and damage had been done to the extent of about 2,500,000 dollars. With such an event coming suddenly upon them, they could imagine how the people were prostrated. The heart of the people was completely crushed. A great many of the sufferers were of the poorest class, and they were almost powerless to help themselves. They were without food, except such as had been supplied to them through the kindness of their neighbours ; they were without clothes, for all their clothes had been destroyed ; and, unfortunately, the working people of the community had been almost entirely bereft of the tools and implements with which they were in the habit of earning their daily bread."

It is indeed very sad to think that this terrible calamity might have been avoided had the oil lamp which was the cause of all this mischief been fitted with a simple application of science in the shape of a simple automatic extinguisher.

July 20. HUMANITY.

THE WASHINGTON COLLECTION OF FOSSIL VERTEBRATES.

WE are pleased to learn from a transatlantic contemporary that the enormous collections of vertebrate remains, obtained under the superintendence of Prof. O. C. Marsh from the Tertiary and Secondary strata of the north-western United States, are about to be transferred to the National Museum at Washington, where they will eventually be properly arranged, and exhibited to the public. For the last nine years, as we are informed, the United States Government has voted funds for the collection and preservation of these wonderful remains, descriptions of which have been from time to time presented to the scientific world with a wealth of illustration which cannot but render European palæontologists somewhat envious.

Hitherto the whole of this collection (together with Prof. Marsh's private collection) has been stored in the palæontological department of the unfinished Peabody Museum, at Yale College, New Haven, Conn. ; where want of space has totally prohibited its proper exhibition. Indeed, those who have had the opportunity of inspecting this unrivalled series inform us that the specimens are so crowded together—the smaller ones in tier upon tier of trays, and the larger ones on the floors and in every available corner—that it has hitherto been quite impossible to form any adequate judgment as to the extent and importance of the collection. It is, however, satisfactory to learn that the whole series has been carefully labelled and registered, so that the locality and date of acquisition of every individual bone are fully recorded.

To prepare such an enormous collection for transit by rail is a work demanding both extreme care and a considerable amount of time ; while the Museum space required for the exhibition of entire skeletons of the bulk of those of the Jurassic and Cretaceous Dinosaurs must be proportionately extensive. We are informed, indeed, that if the whole collection were transferred to Washington at the present time it would occupy fully one-half of the buildings of the National Museum. Accordingly, only a portion of it is to be immediately transported ; while the remainder is to wait until Congress has provided suitable quarters for its reception. It is to be hoped that the moiety now to be transferred will include a representative selection from the entire series, so that palæontologists will have an opportunity of seeing more or less nearly entire skeletons, not only of the Dinosaurs and other huge Saurians of the Mesozoic, but likewise those of the equally wonderful Tertiary mammals. We may also venture to express the hope that the United States Government will before long see its way to enriching European Museums with some of their duplicate specimens, of which there must be a large number for disposal.

With a wise liberality, the Government of the United States appears to have made a regular business of the collection of these fossils, under the able direction of Prof. Marsh ; this business being conducted much after the manner of any other mining enterprise. One of the favourite hunting-grounds is the region lying between the "Rockies" and the Wasatch Mountains ; and the accounts of the richness of some of these deposits in vertebrate remains is absolutely marvellous. Thus Prof. Marsh is reported to know of one small valley where bones of Mosasaurians are in such profusion that in passing through it he observed at one time no less than six entire skeletons of these monstrous reptiles, each averaging some 80 feet in length. At such a rate of discovery it is no wonder that Museum accommodation cannot be procured fast enough. The care taken to prevent other fossil-hunters from discovering the more productive localities affords rather amusing reading ; but, under the circumstances, it is, perhaps, natural.

Whenever a likely-looking bone or skeleton is seen projecting from a rocky cliff, skilled workmen are at once set to work on its extraction ; a single specimen sometimes leading to the discovery of a regular golgotha of remains. The wonderfully perfect condition of some of these fossils, and the rapidity with which the carcasses of their former owners must have been entombed in sand or mud, are brought prominently under notice by a recent reported discovery in Wyoming. This is said to be nothing less than the disentombment of an entire skeleton of that stupendous Dinosaur known as the Brontosaur, in which not only is every bone in place, but an actual mould of the surface of the eye, formed in the sand upon which the creature lay, has been preserved in the solid rock.

Prof. Marsh's restoration of the Brontosaur—a creature 60 feet in length, walking on all fours, with an enormously long neck and tail, a disproportionately small head, and the bony substance of its backbone reduced to a mere shell and a honeycombed interior—has been long before the world. Less known, however, is his later reconstruction of the skeleton of one of the gigantic horned Dinosaurs from the Laramie Cretaceous, which he calls *Triceratops;* the skull and pelvis of which were referred to in an earlier number of NATURE. In this restoration the Professor has certainly succeeded in producing a most marvellous animal, although, so far as we see, the figure appears to be true to nature. It will be remembered that one of the most remarkable features in the skull of *Triceratops* (which in some specimens was upwards of 12 feet in length) is the production of the hinder regi on into a huge fan-like shield, the use and purpose of which it was at first a little difficult to understand. This is, however, explained by the restored skeleton, where we see this shield overlapping and protecting the first six vertebræ of the neck; to which additional strength was imparted by the bony union of several of them. In the shortness of its neck and the enormous size of its skull, *Triceratops* presents a striking contrast to *Brontosaurus.* Like the latter, however, it habitually walked on all fours; while in correlation with its massive skull its fore-limbs were relatively stouter than in any other Dinosaur. In this respect it differs widely from its near ally, *Stegosaurus*, which, at least occasionally, walked in a bird-like manner; and since *Triceratops* is evidently a more specialized creature than *Stegosaurus*, the suggestion arises that the former has undergone a retrograde development from a bipedal to a quadrupedal mode of progression. No attempt has yet been made to represent the position on the skeleton of the dermal bony armour with which many parts of the body of *Triceratops* were protected during life; the precise position of the various spines, knobs, and plates, which have been found in association with the bones, being largely a matter of conjecture. The size in life of the restored example would be approximately some 25 feet in length by 10 in height; but these dimensions must have been exceeded by other specimens.

By the completion (so far as anything connected with fossils can be said to be complete) of our knowledge of the skeleton of *Triceratops*, we are acquainted with the bony framework of all the chief types of Dinosaurian reptiles at present known. These may be classed as the Sauropodous type, as represented by *Brontosaurus;* the Theropodous type, as represented by *Megalosaurus* and its allies; and the Ornithopodous modification, represented on the one hand by *Iguanodon*, and on the other by *Stegosaurus*, *Triceratops*, &c.

In the contemporary publication to which we have referred some interesting suggestions as to the probable habits of these Dinosaurs are put forth, although how far they will meet with acceptation remains to be seen. Thus it is suggested that the honeycombed vertebræ of the Brontosaurs and their allies were filled with warm air from the lungs (which assumes that these reptiles were warm-blooded), by which means their bodies were partly floated when they wandered out of their depth in the sea shallows, from whence they stretched their long necks to crop the seaweed near the shore. Again, the long hind legs of the Hadrosaur (an ally of our Iguanodon) are considered to have enabled their owner to wade far out to sea in search of seaweeds growing on the ocean-floor; while the armoured kinds, like *Stegosaurus* and *Triceratops*, are considered to have been essentially terrestrial.

As we have indicated, the great bulk of the collection is composed of Secondary reptiles and Tertiary mammals; and from their large size it is these which form its most striking feature. We most not omit to state, however, that it also contains the Toothed Birds from the Cretaceous of Kansas (of which our English collections do not at present possess a single bone), as well as hosts of teeth of Mesozoic mammals, although we have no definite information as to what proportion of these are the property of the State, and what belong to Prof. Marsh. Then, again, scattered among the trays and drawers more especially devoted to the remains of mammals and reptiles is an extensive collection of fish-remains from Cretaceous and Tertiary strata, and especially from the Green River Eocene shales of Wyoming, most of which we believe to be at present totally undescribed.

Space prevents us from saying more as to the extent of this marvellous collection—a collection which, with others from the same regions, has done more in ten years to revolutionize our classifications, and to give us a definite knowledge of many groups of animals previously known by battered fragments, than would have resulted from half a century's work upon European materials. We may, however, conclude by offering our hearty congratulations to the Governments of the United States and to Prof. Marsh, who have succeeded, by the liberality of the one and the untiring energy of the other, in amassing this magnificent collection, which is now, for the first time, in a fair way to be exhibited in a manner befitting its value and importance. Prof. Marsh's magnificently illustrated monographs on the Toothed Birds and the Dinocerata are splendid examples of how a collection like this ought to be made known to the scientific world at large; and we trust ere long to be able to welcome his long-promised volumes on the Dinosaurs and the Brontotheres, which will render its riches yet better known.

R. LYDEKKER.

DYNAMO-ELECTRIC MACHINERY.[1]

THIS is the first part of a treatise dealing with dynamo-electric machinery and its applications, and comprises the theory and practical construction of dynamos and motors, and an account of instruments and methods of electrical measurement. Such subjects as the fusion and welding of metals by electricity and the transmission of power are reserved for a second part, to be issued in the autumn of the present year.

The author begins with a chapter entitled "Generalities regarding Dynamos," in which he discusses the early rudimentary magneto-machines of Pixii and Clarke, and the multipolar machines of the same class invented by Stöhrer and Niaudet, gives a general explanation of the self-excitation and action of series of shunt and compound dynamos, and describes the various typical forms of armature used in constant and alternating-current machines. In this part there is room for little novelty of treatment; the author could only endeavour to be impartially historical and clearly descriptive, and give as complete and useful an account of the more important examples of dynamo machinery as his space would admit of. In this Signor Ferrini seems to have succeeded very well. He does not weary his readers with descriptions of mere antiquities, but supplies only such a brief account of earlier forms as is sufficient to enable the reader to trace the evolution of the modern constant-current dynamo, with its beautiful balance and inter-relation of parts, from the rudimentary, uneconomical, and violently periodic machine of twenty years ago, or to compare the powerful alternator of the present day with the ineffective and wasteful toy instrument, which used to figure in cabinets of apparatus and the older books on electricity.

---

[1] "Recenti Progressi nelle Applicazioni dell' Elettricità di Rinaldo Ferrini." Parte Prima: Delle Dinamo. (Milano: Ulrico Hoepli, 1892.)

Chapter ii. deals with magnetic induction, and chapter iii. with the induction of currents by the motion of conductors in a magnetic field. These extend over almost 100 pages, or about one-fourth of the whole volume, a space none too large for the subject, but perhaps a little out of proportion to that devoted to dynamo machinery, which is still further restricted by the allocation of fifty pages in chapter iv. to methods of measurement.

Signor Ferrini's treatment of the theoretical part of his subject seems on the whole marked by completeness and accuracy. He has evidently given careful attention to the late developments of magnetic research, and in his chapter on measurements has included most of the improvements recently made, such, for example, as the methods of measuring power, &c., in the circuits of alternators and transformers which have been invented by Ayrton and others. No mention is made, however, of Blakesley's ingenious "split dynamometer" method for transformers, and determining the difference of phase of two alternating currents. Nor is the method (p. 171) of finding the true mean activity in an alternating current from the apparent activity attributed to its inventor, Prof. Ayrton.

We notice here a few points which have occurred to us in looking over this part of the book as perhaps calling for remark. First of all with respect to the definition of a uniform magnetic field given at p. 58, it may be noticed that if the numerical value of the intensity of the magnetic force be the same at all points of a finite space, its direction must be the same at all points of the same space, and that the intensity cannot vary in magnitude from point to point without varying also in direction, and *vice versâ*. This does not seem to be generally understood, at any rate it is common to define a uniform field as one for which the magnitude *and the direction* of the magnetic force are the same at every point. That the former implies the latter, and the latter the former, may be seen by considering a closed surface formed by a portion of a tube of force, in the field, intercepted between two equipotential surfaces. The cross-sections at the two ends must have the same area, since the magnetic force at each end is the same. Further, the lines must be straight, for if they be supposed curved, the portion of the tube may be taken so that it is concave on one side and convex on the other. The line-integral of magnetic force round a closed circuit, taken along the convex and concave sides and across the ends, vanishes. But nothing is contributed to it by the ends of the tube. Hence the magnetic force along the convex side must be on the whole less than that along the shorter concave side, which contradicts the supposed uniformity of magnitude of the field-intensity.

At p. 66 difference of potential, V_1-V_0, between two points is defined as the work which must be done against magnetic forces in carrying a *unit* magnetic pole from the point of lower to that of higher potential; and at p. 74, where the field of a solenoid is considered, $-dV/dx$ appears as the force on a pole of strength m.

At p. 81 mention might have been made of the influence of mechanical stress and disturbance on the magnetization of iron observed by Lord Kelvin and others, and of the fact that very much higher permeabilities than the 2000 quoted from Rowland's experiments have been obtained by Ewing for soft iron subjected to molecular vibration produced by tapping.

The subject of hysteresis is dealt with at p. 91, and again at p. 235 in the chapter on the construction of a continuous-current dynamo. In the latter place a proof is furnished of the well-known formula given by Warburg in 1881 or 1882, and a little later by Ewing, for the energy dissipated in a closed cycle of magnetization. In the course of that proof, to which in itself we take no exception, one or two statements are made which, if we have understood the author aright, are erroneous. It is stated that when the integral induction Φ through each turn of a magnetizing helix of n windings, each carrying a current c, is increased by an amount $d\Phi$, a quantity of energy $= - ncd\theta$ $(= - v\mathbf{H}d\mathbf{B}/4\pi)$, where v is the volume of the medium magnetized, $\mathbf{H}$ the field intensity and $\mathbf{B}$ the induction, both supposed uniform) is given out by the spiral *and converted into heat*. Now (the sign being left out of account) this is certainly the energy sent into the field from the battery or generator, but it is not the case that it is all converted into heat. The amount of energy spent in unit volume of the magnetized medium is $\mathbf{H}d\mathbf{B}/4\pi$, but of this $(\mathbf{H}d\mathbf{B} + \mathbf{B}d\mathbf{H})/8\pi$ goes to increase the electrokinetic energy, the amount of which per unit volume of the medium is $\mathbf{BH}/8\pi$. The total amount of energy spent per unit volume in the cycle of magnetization, otherwise than in increasing the electrokinetic energy, is therefore

$$\frac{1}{4\pi}\int\left\{\mathbf{H}d\mathbf{B} - \frac{1}{2}(\mathbf{H}d\mathbf{B} + \mathbf{B}d\mathbf{H})\right\},$$

the integrals being taken round the cycle. (It is to be noticed that this balance of energy may be negative, and in that case energy is taken from the field to make up the increase of electrokinetic energy.[1])

But for a closed cycle

$$\int(\mathbf{H}d\mathbf{B} + \mathbf{B}d\mathbf{H}) = 0,$$

and hence the energy spent is

$$\frac{1}{4\pi}\int\mathbf{H}d\mathbf{B}.$$

This must have been dissipated, since the medium at the end of the cycle has returned to the same state as at first.

No affirmation can be made as to what becomes of the balance of energy, except with reference to a closed cycle.

Again, at p. 237 it is stated that if $\mathbf{H}_1$, $-\mathbf{H}_1$, be limits of $\mathbf{H}$ corresponding to limits $\mathbf{B}_1$, $-\mathbf{B}_1$ of $\mathbf{B}$,

$$\int_{-\mathbf{H}_1}^{\mathbf{H}_1}\mathbf{H}d\mathbf{B} = \int_{-\mathbf{B}_1}^{\mathbf{B}_1}\mathbf{B}d\mathbf{H}.$$

This is certainly not correct, as may be easily seen by representing the integrals graphically, or by considering that taken round a closed cycle

$$\int\mathbf{B}d\mathbf{H} = -\int\mathbf{H}d\mathbf{B},$$

since

$$\int(\mathbf{H}d\mathbf{B} + \mathbf{B}d\mathbf{H}) = \int d(\mathbf{BH}) = 0$$

for the cycle.

This error, a mere oversight no doubt, has appeared more than once in connection with this subject, and an erroneous demonstration founded on it and a mistaken identification of the energy dissipated with the electrokinetic energy, has been used by more than one writer.

The chapters on the "Continuous Current Dynamo," the "Dynamo in Action," and "Alternating Dynamos," are excellent in many respects. The subject is well and fairly comprehensively treated, and the very useful notion of the magnetic circuit has been employed throughout with good effect. Some well-known machines do not seem to be described, for example, the Victoria among continuous-current machines, and the latest form of Mordey's alternator.

---

[1] See a paper by the writer in the *Phil. Mag.*, December 1890.

The inclusion of a larger number of thoroughly practical examples of dynamo specification and construction would also be an improvement.

On the whole, Signor Ferrini's book seems the outcome of an earnest endeavour to give an accurate and full account in moderate compass of an important and difficult subject. It will be more easy to judge of the full measure of the author's success when the work is completed. In any case the book seems likely to be a credit to Italian technical literature. A. GRAY.

MR. A. NORMAN TATE.

BY the death of Mr. A. Norman Tate, F.I.C., Liverpool has lost one of her most prominent citizens and men of science. It is not only as an able analytical chemist that Mr. Tate will be missed by a large section of the public to whom his genial presence was familiar, but as a scientific teacher and pioneer of the technical education movement in Lancashire, his place is one that will not easily be filled. For some time past Mr. Tate has had indifferent health, and has had to give up much of his active work in connection with the Society of Chemical Industry, of whose Publication Committee he was a member, and the numerous local and other learned societies to which he gave great aid. Latterly, symptoms of an ulcerous tumour in the stomach presented themselves, from which he died on the 22nd instant.

Mr. Norman Tate was a native of Wells, Somerset, and came to Liverpool about thirty-five years ago, when he entered the laboratory of the late Dr. Sheridan Muspratt. He published several papers bearing on his early researches in the journals of the Chemical Society of London and the Royal Dublin Society. After acting for some years as chemist to the firm of John Hutchinson and Co., of Widnes, he commenced practice as an analyst in Liverpool, and became consulting chemist to several important local bodies and chemical manufactories. At that time the importation of petroleum from America was beginning, and on this subject Mr. Tate became an authority; one of his works, "Petroleum and its Products," being translated and re-published in France and Germany. For a time Mr. Tate superintended the working of oil refineries in the Isle of Man and in Flintshire, where he erected a manufactory for the production of coal and shale oils. In 1870, Mr. Tate, in conjunction with Mr. James Samuelson, undertook the initiation of the Liverpool Science and Art Classes, which grew to be a great educational power in the city. As honorary principal, Mr. Tate had charge of these classes, besides giving lectures himself and teaching several of the classes in chemistry, botany, and general biology. He also instituted the Liverpool Science Students' Association, and the Liverpool District Science and Art Teachers' Association, of both of which bodies he was the first president, a post he also filled in the local Geological Association, Microscopical Society, Liverpool Section of the Society of Chemical Industry, and other institutions, contributing largely to their "Transactions." The "Proceedings" of the Liverpool Geological Society also contain many of his papers and memoirs. He discovered the presence of iserine in the decomposed greenstones of the Boulder Clay in the Valley of the Mersey, and showed that the black colour of certain sandstones in the trias in the neighbourhood of Liverpool is due to the grains being coated with peroxide of manganese.

Mr. Tate was an ardent supporter of every educational movement, especially in connection with science teaching, and his death, at the early age of fifty-six, will be much deplored by a circle of friends extending far beyond the limits of the city which he had made the chief scene of his labours. O. W. J.

THE BRITISH ASSOCIATION.

EVERYTHING is now practically ready for the meeting of the British Association, which begins next week, and promises to be in every way most successful. Many distinguished foreign men of science—among them Helmholtz, Cremona, and Sachs—are expected to be present. The arrangements made by the local committee we described last week.

In compliment to the President there will be a specially strong muster of geologists. We hear that a number of professors and others connected with the Geological Survey of France are coming. Baron von Richthofen and Prof. Credner will represent the geologists of Germany; Prof. Renard those of Belgium. There will be many other representatives from different countries in Europe and from America. The geological excursions will likewise form a prominent feature in the proceedings, and one of these is to be conducted by the President of the Association in person. The Prince of Monaco, well known for his scientific researches, intends to bring his deep-sea dredging vessel to Granton, and to read a paper on the results of his marine surveys; while two members of his scientific staff will communicate papers on some of the natural history objects obtained by them. Already a large amount of hospitality has been organized, and the meeting bids fair to be as successful in a social as in a scientific way.

We have already announced that at the meeting of Section A. on Monday, August 8, a discussion on the subject of a national physical laboratory will be opened by Prof. Oliver J. Lodge, F.R.S.

A meeting of the Electrical Standards Committee will be held on Thursday, August 4. It is expected that Dr. von Helmholtz, Dr. Lindeck of the Berlin Reichsanstalt, and others interested in electrical measurements, will be present. A discussion will take place with a view to securing an absolute uniformity in the standards adopted in England and elsewhere. The following points will be considered:—(1) The value of the B.A. unit in ohms; (2) the specific resistance of mercury in ohms; (3) standardizing by the electrolysis of silver; (4) the electromotive force of a Clark cell; (5) Report of the Committee for 1892. It is proposed to take the report of the Committee in Section A. on Tuesday, August 9. The draft prepared by the secretary is formal; but it is hoped that the discussion in the Committee may lead to some resolutions, which will be included in the report.

The proceedings of Section D. promise to be exceptionally interesting. The President's address will relate to some qualities of sensation, with special reference to colour sense. On Friday there will be a joint discussion with B. on chemical aspects of the action of Bacteria, which will probably be opened by Prof. Marshall Ward. On Monday there will be a discussion on some matters connected with sea-fishes and fisheries, in which the following will read short papers or take part:—Sir J. Gibson Maitland, Prof. M'Intosh, Prof. Ewart, Dr. Fulton, Prof. Herdman, Mr. E. Holt, Mr. R. Smith, Mr. G. Brook, &c.

NOTES.

THE summer meeting of the Institution of Mechanical Engineers, to which we referred last week, began at Portsmouth on Tuesday, under the presidency of Dr. William Anderson, F.R.S. The president, council, and members were received by the Mayor, who cordially welcomed them to Portsmouth.

THE British Medical Association's sixtieth annual meeting was opened at Nottingham on Tuesday, the chair being occupied by Dr. W. Withers Moore. In his presidential address Dr. Moore dealt with the progress which has been made in surgery and medicine since 1857, when the Association held its last meeting at Nottingham.

A GENERAL meeting of the Sanitary Inspectors' Association was held at Carpenters' Hall, London Wall, on Saturday evening last, the president, Dr. B. W. Richardson, presiding. The council presented a report upon the question of examination for sanitary inspectors, recommending that they should be empowered to confer with the court of the Carpenters' Company in order to arrange for lectures and examinations. The report was adopted. A report upon the association's recent visit to Paris was also presented, setting forth the principal features and incidents of the journey. The adoption of this report was moved by Mr. Alexander, and seconded by Mr. Tidman. The chairman, in supporting the motion, said the association had learned many important lessons upon the question of sanitation by their visit to the French capital. After comparing the French and English systems of sanitation, he expressed the opinion that in the matter of disinfection the English might learn much from their French neighbours. He believed that in London there might with advantage be established one or more grand centres for disinfection such as existed in Paris. He deprecated the system in use at the Paris Morgue of freezing dead bodies for the purpose of identification as being, in his belief, utterly useless for that purpose. On the question of the inspection of animal food, he thought that England could not do better than follow the system adopted in France of testing every doubtful animal before it went to the shambles. A discussion followed, and on the motion of the chairman an ambulance committee was formed to report on the ambulance system in London. The report was adopted.

AN official telegram received at the Hague from Batavia confirms to some extent the statement made at Sydney as to a terrible volcanic eruption in the island of Great Sangir. The volcano which caused the disaster is named Gunona Awu. The telegram adds that the whole of the north-western portion of the island was entirely destroyed, 2,000 persons being killed. The victims included no Europeans. The rest of the island has also suffered seriously by the eruption, but it is hoped that the damage may be repaired in the course of six months. The crops have been destroyed.

FOR some days the eruption of Mount Etna seemed to be gradually decreasing, but on Tuesday it was again very violent, and there were loud subterranean noises. On Monday evening there was a shock of earthquake at Mineo, thirty-seven miles to the south of the volcano. A correspondent of the *Times*, writing from Catania on July 18, says that the exact seat of the eruption cannot be discovered from that city on account of the dense masses of smoke with which that side of the mountain is enveloped, but from Augusta, a town situated about 15 miles away, the summit and western outline are to be seen standing out in bold prominence against the deep, gentian-blue of the Mediterranean sky, and, with its endless volumes of steam and smoke rolling away to the eastward, Etna presents an indescribably imposing, not to say majestic, appearance. From this little town the scene is sublime.

THE cause of the terrible disaster at St. Gervais is now being investigated by several men of science. There can be no doubt that it originated in the small glacier called the TêteRousse, which is nearly 10,000 feet above sea-level. According to a correspondent of the *Times*, who writes from Lucerne, Prof. Duparc is of opinion that the habitual drainage of this glacier had for some reason or other become either totally blocked or obstructed; the water gradually accumulated in its natural concavity or bed; and the ever-increasing volume had exercised such an enormous pressure as to force a passage and carry away a portion of the face of the glacier with it. The mass of ice and water rushed down the rocks which dominate the glacier of Bionnassay, not in a single stream but in several, and then reunited into one enormous torrent at the foot of the Bionnassay glacier. A different theory is held by Prof. Forel, of which the correspondent of the *Times* gives the following account:—Professor Forel does not see how a quantity of water sufficient to force away so large a portion of the glacier could possibly accumulate in so small a body as the Tête Rousse, which has a total superficies of less than one hundred acres. It slopes freely on three sides; it is, in fact, one of the most abrupt of the whole chain of Mont Blanc; and, in a glacier of this description, with an altitude of nearly 10,000 ft., there are none of the conditions of a great accumulation of water. In his opinion, therefore, we must look for the main cause of the disaster in the natural movement and breaking up of the glacier. He estimates the volume of ice which fell at between one and two million cubic metres. The mass, first in falling and then rushing down the rapid slope, became transformed, for the most part, into what he calls a lava of ice and water. The ravine, he says, through which this avalanche rushed shows no traces of any great evacuation of water; in the upper portions of its transit there is no mud and no accumulation of sand, but, on the other hand, there are great blocks of glacier ice strewn everywhere, and at several points he found portions of powdered ice mixed with earth. Then, again, if this had been simply a torrent of water falling, it would have found its way down the more violent inclines, instead of, as in this case, passing straight over the frontal moraine at the foot of the glacier. In this higher region, therefore, all the evidence points to an avalanche of ice, which, starting at an altitude of nearly 10,000 ft., and descending at an incline of 70 per cent. for 5,000 ft., was pulverized by its fall, a large portion of it being melted by the heat generated in its rapid passage and contact with matters relatively warm. It rushed into the ravine by the side of the glacier of Bionnassay and joined the waters of the torrent which issues therefrom, and, further aided by the stream of Bon Nant, it became sufficiently liquid to travel down the lower portions of the valley at the slighter incline of 10 per cent., and yet retained sufficient consistency to destroy everything in its passage. That this torrent was not composed merely of mud and water is proved, he says, by the fact that it did not always maintain the same height when confined to the narrower ravine, and that the remains on the sides of the rock show it to have been a viscous substance rather than fluid.

AN entire change of weather set in over these islands during the past week. The severe storm referred to in our last issue passed quickly to the south-eastward across the Channel, and subsequently traversed Switzerland and Italy. This was succeeded by an area of high barometer readings, which reached this country from off the Atlantic, and extended eastwards over a great part of Europe. Anticyclonic conditions have since been very persistent, with an unusual amount of cloud, especially in the north and south, and, occasionally, mist or fog, but the weather was otherwise fine and very dry. Temperature remained low, under the influence of northerly and easterly winds, the maxima seldom exceeding 70°, while the night minima have also been low, especially over the inland districts of England, where, in places, readings have fallen to within 10° of the freezing point.

THE Vatican Observatory, recently established by Pope Leo XIII., has issued volume ii. of its "Pubblicazioni," containing the results of the most important researches undertaken at the observatory, together with a summary of the proceedings of the meetings held in the year 1891, which comprise a collection of notices relating to astronomy and terrestrial physics. Prof. J. Buti contributes papers (1) on the variations of temperature at different heights. The maxima were generally highest at the lower station, especially in spring and summer, while in winter the conditions were reversed. The mimima were higher throughout the year at the higher station than those near the ground. These results are in accordance with those obtained by the director, Padre Denza, in the case of observations taken at Turin. (2) On rainfall at different heights. The results show that the amount of rainfall is greater at the higher station at times of heavy rain, and conversely at times of slight rain. (3) Comparisons of relative humidity, tension of vapour, and temperature, accompanied by curves. The work also contains hourly observations from January to June, photograms of lunar regions, phototypes of some constellations and nebulæ.

AS an illustration of the specialization of scientific teaching on the Continent, we may mention that Dr. H. Schinz has been appointed Professor of Systematic Botany at the University of Zürich, in order that Prof. A. Dodel may devote his course of lectures entirely to Anatomical and Physiological Botany.

GENERAL PARIS, of Dinard (Ille-et-Vilaine, France), is engaged in the preparation of a *Nomenclator Bryologicus*, on the plan of Steudel's "Nomenclator Botanicus." He will be greatly obliged if bryologists of all countries will send him copies of recent memoirs, or an exact reference to the description of all new species, accompanied, where possible, by a specimen.

A NEW botanical publication has made its appearance under the title *Arbeiten aus dem K. Botanischen Garten zu Breslau.* It is edited by Prof. Prantl and will be devoted to the record of work done in the Botanic Garden at Breslau. The first number contains a paper by Prof. Prantl, on the Classification of Ferns, one by Herr Pomrencke on the structure of the wood of certain gamopetalous families, and one by Herr Mez on the Lauraceæ.

IN addition to the Vascular Cryptogams collected under the auspices of the West India Exploration Committee by Mr. R. V. Sherring, F.L.S., in the island, and described in the *Annals of Botany*, Vol. vi., No. 21, April, 1892, by Mr. J. G. Baker, F.R.S., his collections at Kew have yielded about thirty species of Orchids from Grenada, some of which are of considerable interest. They have now been determined by Mr. R. A. Rolfe, A.L.S. The orchids of Grenada appear not to have been systematically collected before. There are no records of species from that island in Grisebach's *Flora of the British West India Islands*, 1864, and only about three or four were represented in the Kew Herbarium. Mr. Sherring's collections, therefore, enable us to arrive at a tolerably good idea of the distribution of orchids in the island. A species of *Brachionidium*, a genus not hitherto represented in the West Indian flora, is probably new, as also species of *Scaphyglottis* and *Cranichis*. *Hexisia reflexa*, *Pleurothallis pruinosa*, *Oncidium luridum* and *Ornithocephalus gladiatus* have not hitherto been found in the smaller islands, the recorded specimens being chiefly from Jamaica and Trinidad. *Dichœa hystricina* has not been found before except in Cuba by Wright and Eggers. *Xylobium* (*Maxillaria pallidiflora*) was recorded before only from St. Vincent, and *Elleanthus lepidus* is new to the West Indian flora. The remaining species are found in many islands, such as Jamaica and Dominica, but their occurrence still further south is a point of some interest.

THE City and Guilds of London Institute has issued a list of the candidates who have passed its examination for the teacher's certificate in manual training. The examination is limited to teachers in public elementary schools. It was held this year for the first time, and related to woodwork. As a large number of teachers had been receiving manual instruction before the institution of the examination, a limited number of candidates were allowed to present themselves for the final examination without having passed the first year's examination. There were 275 candidates for the first year's examination, and of these forty-seven passed in the first class, 108 in the second, and 120 failed. For the final examination there were 340 candidates, of whom forty-nine passed in the first class, 146 passed in the second class, while 145 failed. The examiners report, as regards the first year's examination, that the practical wood-working was uniformly well done, but that the drawing was badly done by a large number of candidates. "It is obvious," they add, "that the instruction in practical drawing is not good. Many candidates failed even to understand the examination paper." In the advanced examination the drawing was much better.

THE Yorkshire College, Leeds, has issued the first report of its department of Agriculture. We are glad to note that the County Lectures to farmers have, as a whole, been successful beyond the most sanguine anticipations of the committee. The unsympathetic attitude which the farmers at some of the centres assumed at first with respect to these lectures was often speedily changed to warm appreciation, which rose, in certain cases, to enthusiasm. The attendance, which was sometimes small at the beginning, grew larger and larger as the course proceeded, and although it afterwards fluctuated for various reasons, the chief of which was the unfavourable state of the weather, which in sparsely populated districts made a journey to the lecture a matter of considerable time and difficulty, the average attendance was extraordinarily good. To the classes and practical demonstrations, which followed many of the lectures, a considerable portion of the audience remained, and their eager participation in the discussions and tests, which formed a conspicuous part of the work of these classes, was extremely encouraging to the lecturers.

AT a meeting of the London Chamber of Commerce on Monday, Mr. J. Ferguson read a paper on "The Production and Consumption of Tea, Coffee, Cacao (cocoa), Cinchona, Cocoanuts and Oil, and Cinnamon, with reference to Tropical Agriculture in Ceylon." He referred to the position of Ceylon, its forcing climate, its command of free cheap labour, and its immunity from the hurricanes which periodically devastated Mauritius, from the cyclones of the Bay of Bengal, and from the volcanic disturbances affecting Java and the Eastern Archipelago. The plantations of Ceylon afforded, he said, the best training in the world for young men in the cultivation and preparation of tropical products, and in the management of free coloured labour. The cultivation of cane sugar, although tried at considerable outlay on several plantations forty and fifty years ago, proved a failure. More recently experiments by European planters with tobacco had not been a success, nothwithstanding that the natives grew a good deal of a coarse quality for their own use. Although cotton growing had not been successful, the island had proved a most congenial home for many useful palms, more particularly the coconut (spelt without the "a" to distinguish it and its products from cocoa—the beans of the shrub Theobroma cacao) and palmyra, as also the areca and kitul or jaggery palms. Within the past few years Ceylon had come to the front as one of the three great tea-producing countries in the world, India and China being the other two, with Java at a respectable distance. Mr. Ferguson said one of the chief objects of his pape was to demonstrate which of the products of the island it was safe to recommend for extended cultivation in new lands and which were already in danger of being over-produced, and he had arrived at the conclusion that coffee, cacao, and rubber-yielding trees were the products to plant, while tea, cinnamon, cardamoms, cinchona bark, pepper, and even palms (for their oil) did not offer encouragement to extended cultivation. Statistics relating to the total production and consumption were given in an appendix.

AN interesting paper on Indian types of beauty was read some time ago by Mr. R. W. Shufeldt, before the Philosophical Society of Washington, and has now been issued as a pamphlet. It is admirably illustrated.

MR. A. G. HOWES, British Consul at Tahiti, in his latest annual report to the Foreign Office, has the following note respecting pearl-shell diving in Tahiti:—Since the introduction of the diver's dress and apparatus at the pearl fisheries in 1890 a considerable increase in the export of shell has been maintained over the previous years. A strong feeling has, however, been exhibited by the natives, who adhere to their own system of diving, against this means of taking the shell, and has resulted in a communication being made by the Director of the Interior of the colony to the Chamber of Commerce at this place, recommending the gradual abolition of the diving dress and apparatus and the stoppage of further issue of patents for the same, from January 1, 1893. The Chamber of Commerce have expressed their approval of the suggestion, but consider that an entire and not gradual abolition of the diving dress and apparatus should take place, and they have decided to lay this proposal before the Conseil-Général when it assembles next August. The reasons set forth by the Chamber of Commerce for adopting this course are that the regulations for the use of the diving dress and apparatus have been abused. They state that French citizens, contrary to rule, have under their name employed diving dress and apparatus owned by foreigners; that the law prohibiting pearl fishing by this means in a depth of less than ten fathoms had not been adhered to, and they also give as their opinion that the shells found in a greater depth than ten fathoms are those mostly important for reproduction, and to destroy them will ruin the fisheries and bring distress upon the natives who depend upon the pearl-shell diving for their livelihood.

THE additions to the Zoological Society's Gardens during the past week include a Common Marmoset (*Hapale jacchus*) from South-east Brazil, presented by Mr. Gerald F. Youll; an African Civet Cat (*Viverra civetta*), a white-tailed Ichneumon (*Herpestes albicauda*), two Ostriches (*Struthio camelus* ♀ ♀) from East Africa, presented by Mr. F. Pardage; a Pine Marten (*Mustela martes*), British, presented by Mr. Harold Hanauer, F.Z.S.; three North American Turkeys (*Meleagris gallo-pavo*) from North America, presented by Col. H. W. Feilden, C.M.Z.S.; two Rufous-necked Wood Doves (*Haplopelia larvata*) from South Africa, presented by Mr. W. H. Wormald; a Grand Eclectus (*Eclectus roratus*) from Moluccas, presented by Messrs. Chas. and Walter Seton; two Red-crested Cardinals (*Paroaria cucullata*) from South America, presented by Miss Edith M. Fox; a Common Chameleon (*Chamæleon vulgaris*) from North Africa, presented by Mast. S. E. Thorns; a Large Brown Flying Squirrel (*Pteromys oral*) from the Shevaroy Hills, South India, three American Bisons (*Bison americanus* ♀ ♀ ♀) from North America, a Barraband's Parrakeet (*Polytelis barrabandi*) from New South Wales, deposited; a Mongoose Lemur (*Lemur mongoz*) from Madagascar, purchased; an American Bison (*Bison americanus* ♀) from North America, received in exchange.

OUR ASTRONOMICAL COLUMN.

MADRAS OBSERVATORY.—This year being the centenary of the founding of the Madras Observatory, the officiating astronomer, Mr. C. Michie Smith, prefaces his report with a brief historical sketch. It seems that the East India Company were the first to propose the establishment of such an Observatory, but Sir Charles Oakeley, taking time by the forelock, and, as we are informed, anticipating the orders from the India Office, set about constructing it on his own authority. With the aid of Mr. William Petrie, who placed his own observatory at their disposal, the scheme was soon brought to a practical head, and by the time the orders arrived in 1792 the Observatory, besides being actually built, contained many instruments. The first astronomer was Mr. J. Goldingham. Mr. Thomas Glanville Taylor, F.R.S., was Director of the Observatory from 1830 to 1848. After erecting new instruments, he began his catalogue of 11,000 stars, publishing it in the year 1844. Hourly meteorological and magnetic observations were also carried on by him. He died in England in May 1848, having never completely recovered from a serious injury caused by a fall. In 1849 Captain W. S. Jacob was appointed astronomer; he made a new departure in the form of extra-meridional observations. Owing to ill-health Captain Jacob resigned his appointment in 1859, and during the next two years the office was held partly by Major W. K. Worster, R.A., and Major (now General) J. F. Tennant, R.E. About this time the work of the observatory was delayed, as more modern instruments were being erected, and it was not till May 1862 that the new transit circle of 5 inches aperture and 42-inch circle was ready for use. The late Mr. N. R. Pogson, who had then arrived in Madras as Government Astronomer, commenced his catalogue of 5,000 stars, observing each at least 5 times. He also used very considerably the 8-inch equatorial. The present astronomer, Mr. C. Michie Smith, in his report, suggests a further increase of the observatory equipment.

OXFORD UNIVERSITY OBSERVATORY.—During last month the seventeenth annual report of the Savilian Professor of Astronomy was presented to the Board of Visitors of the University Observatory. This report showed that the work of the Observatory during the past year has been very considerable. The Grubb equatorial, the transit circle, and the De la Rue equatorial have been severally occupied, while the new micrometer for the Grubb instrument has worked efficiently, and forms a valuable addition to the resources of the Observatory. The work upon the international chart has formed one of the important features throughout the year, and for the measurement of the photographic plates a new and costly form of micrometer had to be devised; the réseaux have not proved to be very enduring, so that in consequence a new one had to be obtained from Messrs. Gautier of Paris. The work connected with stellar parallax has now been completed after a period of four years' hard work, and this fact deserves the highest consideration in face of the magnitude of the staff and the amount of work done. The manuscript consists of (1) the concise but complete history of all effective researches in stellar parallax up to the present date; (2) the results of the parallax work completed in this Observatory, extending on the whole to some thirty stars; (3) a catalogue of all parallactic determinations effected by other astronomers. Among some of the other work commenced or completed during the present year we may mention the photometric catalogues of stars of the ninth and eleventh magnitudes within small specified areas for the eighteen Observatories engaged in the international chart, observations of Nova Aurigæ, and the investigation of the amount of light "lost by the moon at the commencement and termination of the lunar total eclipse on November 15, 1891." The finances of the Observatory at present, owing to previous economy, seem to cover the expenditure, but Prof. Pritchard seems to refer to the fact that the quinquennial grant expires at the end of the present year, as if next year the University will be called upon to make a slight additional increase to counterbalance the cost of the instrumental equipment that has been required for the chart work. We are glad to note that at this meeting of the Board Prof. Pritchard was able to attend, having completely recovered from his illness.

GEOGRAPHICAL NOTES.

M. DYBOWSKI has returned to France in bad health. His last work in the French Congo territory was an expedition up the Ubangi to avenge the murder of M. Crampel.

THE Royal Belgian Society of Geography has of late been devoting special attention to home affairs, and in particular to the publication of more or less exhaustive monographs of the local geography of the communes. The last number of their *Bulletin* contains an able summary of the geography of the commune of Familleureux, under the main heads of physical, economic, administrative geography and history, with carefully planned subdivisions. By multiplying such studies, the material for a really exhaustive geography of the country will be obtained. Some such scheme might well be applied to the United Kingdom, where a series of county geographies on a definite system and rigorously edited would be peculiarly advantageous. The idea was present in Sir John Sinclair's famous "Statistical Account," but has had no recent or adequate embodiment.

THE *Scottish Geographical Magazine* for July contains a translation by Mr. C. E. D. Black of M. Dauvergne's recent journey in the Pamirs, the original paper appearing simultaneously in the *Bulletin* of the Paris Geographical Society. The journey carried out in 1889-90 was a most successful one and opened up some new ground. The geographical results are summed up in four sentences:—(1) That there is another great chain running parallel to the Kuen Lun and facing Kashgaria. (2) That the river in the Tung valley is an affluent of the Zarafshan, not of the Taghdumbash. (3) That the Oxus rises in the great glaciers of the Hindu Kush at 37° 10' N. and 75° E. (4) That the Karambar valley, although difficult, is practicable for ponies.

DR. THEODOR MENKE, one of the best known of German historical geographers, died in Gotha in May last. His work in the compilation of atlases of historical geography was exceptionally thorough. His first work in this direction was a popular school atlas of classical geography, entitled "Orbis Antiqui Descriptio"; but his most important contribution to cartography was his edition of Spruner's great historical atlas, begun in 1858 and completed in 1879.

DR. STUHLMANN, according to a telegraphic report in the *Times*, has furnished additional particulars of Emin Pasha's expedition, although no more recent news. The real and only aim of Emin's journey to the Equatorial province, was to rescue those of his former subordinates, whose vacillation and delays kept them from joining Stanley's march to the coast. It was then his purpose to make his way across Africa to Adamawa and the Cameroons, a purpose which, as we already know, he had to abandon. It is satisfactory to learn that Dr. Stuhlmann had with him at Bukoba all the valuable scientific records and collections of the expedition.

THE current number of *Petermann's Mitteilungen* calls attention to a curious literary fraud to which in the two previous numbers it fell a victim, and from which many geographical journals in the habit of faithfully reproducing the articles of *Petermann* also suffer. A Dr. Ceyp professed to have made a journey recently in south-eastern Persia, and communicated to *Petermann* a detailed account of it, which now appears to have been copied verbatim from a little-known work, "Gasteiger-Khans," reprinted from the "Boten für Tirol und Vorarlberg," 1881. General Houtum Schindler, of Teheran, who knew that Ceyp's Persian travels had not led him beyond that city, gave the information which led to this discovery. The episode furnishes a fresh proof of the necessity for the great caution in accepting the records of unknown travellers which has always been exercised by the leading English authorities.

THE BEARING OF PATHOLOGY UPON THE DOCTRINE OF THE TRANSMISSION OF ACQUIRED CHARACTERS.

FOR more than two years the English public has been in possession of an excellent translation of sundry of Weismann's more important essays.[1] The object of this paper is not to expound Weissmann's views generally. That office has already been undertaken by the persons best qualified to perform it.[2] We propose merely to discuss one of his topics under a single aspect—the "Transmission of Acquired Characters" in its relations to pathology.

We cannot, however, avoid reviewing some of the leading points in Weismann's system which bear upon our immediate topic.

At the root of the matter lies the all-important distinction between reproductive and somatic cells. Saving among the lowest forms of animal life, an organism may be regarded as made up of two parts. There are the reproductive cells. With these the future of the species lies. They are the visible basis of its perpetuity. The remaining tissues of the body are styled "somatic." It is natural to us to think of the "somatic" tissues as something higher and nobler than the reproductive cells—to contrast the simplicity of the latter in structure and endowment with the intricacy of the former. But there is another point of view, which inverts matters; which regards the somatic tissues—the body and its manifold endowments—simply as a sort of living case or appendage of the reproductive cells. The reproductive cells look after the perpetuity of the species, the somatic cells look after the reproductive cells.

Now, if we travel back to the simplest forms of animal life, we lose sight of this distinction. The principle of differentiation of labour is not yet recognized. Among the Protozoa the distinction between reproductive and somatic cells has no place. Every part of the organism has it in its power to reproduce the entire organism. No special material is reserved to serve the purposes of reproduction. As we ascend in the scale of animal life, differentiation of labour begins. There is from the outset a reservation of reproductive cells, which serve as the demonstrable links between successive generations of organisms. But in sundry of the highest forms of animal life a third condition obtains. There is at the outset no reservation of cells: differentiation overtakes the entire organism—there is no exemption.

Not till the close of embryonic life do the reproductive cells appear, and when they do so it is as the offspring of somatic cells. This third condition was felt by Weismann as a difficulty, and led to an important modification in his terminology. The problem he had to explain was this, How can cells which have apparently lost their reproductive characters afterwards regain them? The solution he found was that the differentiation undergone by certain cells was never in reality thoroughgoing enough to deprive them of their original characters. Sooner or later, a moment arrives at which the original "germ-plasm" becomes again predominant. Instead, then, of in "germ-cells," the basis of perpetuity of the species is laid in "germ-plasm."[1]

We have now to consider the bearing of these views upon the doctrine of the transmission of acquired characters.

It is of the utmost importance to understand precisely what Weismann means by the term "acquired character." Acquired characters are opposed to original characters. To grasp the distinction we are sent back to a time before the distinction between reproductive and somatic cells existed. The characters already present at this early period are original characters. Later on, the reproductive and somatic cells part company, to follow separate careers of their own. It is the somatic cells—the body—which comes chiefly into collision with the environment, and in doing so undergoes various modifications. Now these modifications are the "acquired characters" the transmissibility of which Weismann denies.

They may be something purely local, as a scar or a mutilation. They may be something which involves the modification of complex musculo-nervous mechanisms, as in delicate manipulations and tricks of skill, such as violin-playing. Now, how is it conceivable, he argues, that such specific changes in the somatic tissues should influence the reproductive cells in the same direction? Whether they influence them at all is not the matter in dispute. That they do this is not only conceivable, but highly probable. But how can the somatic cells stamp their own special characters upon the reproductive cells?

We now turn to the main topic of this paper. Has pathology anything to say, either for or against, the transmissibility of acquired characters?

Now, as to the transmissibility of sundry forms of disease there is no question. That pathological characters are transmitted is universally allowed. The difficulty, however, is to decide whether such characters were really acquired, in the strict sense in which Weismann uses the term. We shall find that it will require considerable care to adduce instances which are really appropriate. With this preliminary caution we may proceed to attempt some sort of preliminary classification of our pathological data. We shall find that they fall, roughly, into three main groups:—

(1) Morbid characters which are obviously acquired by the organism, and as obviously transmitted. But since they are in no sense the acquisition of the somatic cells as such, but of the entire organism—somatic and reproductive cells alike—they cannot be allowed to "rank."

(2) Morbid characters in which an element of transmission is obvious, but where a closer investigation reveals the fact that, supposing them to have been acquired, in Weismann's sense of

the word, it is not precisely what was acquired that is transmitted, but something broader and more general.

(3) The cases which are really in point: morbid characters which were really acquired by the somatic tissues alone. We shall see, later, whether or no these are transmitted.

(1) This group embraces all those cases in which a morbid character is acquired by the entire organism, somatic and reproductive cells alike. Behind the distinction between somatic and reproductive cells lies the fact of a common relation to the circulatory and nervous systems. Any change, therefore, in the circulation for example, will affect both. A pregnant woman takes a fever, and transmits it there and then to her offspring. There is no more mystery in this than in the fact that certain poisons produce abortion—indeed, the *materies morbi* is a poison in either case. But this explanation has, in all probability, a much wider range than the zymotic diseases. Consider, for example, gout. In a sense it is no doubt true to say that gout was an acquired disease. We can point to periods in the world's history in which gout was conspicuous by its absence. We can trace with some degree of accuracy its rise and progress at different epochs, and point to the conditions under which it rose, as, for example, in the early days of the Roman Empire.[1]

But even if we allow that gout was, in a general sense, an acquisition of civilized society, we have only to reflect on its pathology to see that it could never have been acquired in Weismann's sense. For what is gout? People usually think of gout by one of its manifestations—inflammation. This, however, is in reality no more than a symptom—perhaps than an incident—of a condition. The gouty attack is due to the existence of certain sites in the system conveniently cool and dry for the deposition of what are popularly known as chalk stones, if, indeed, it be correct to think of the morbid process as a deposition. The general morbid condition lies deeper, and still eludes us. But if we are in the dark as to the precise nature of the pathology of gout, it would be affectation to say that we are unable to prescribe its general outlines. Is it a degeneration, in which the entire organism shares? Then it will be a morbid acquisition of both somatic and reproductive cells alike. Or is it a failure in metabolism generally? The same will be the case. Or is it due to a failure in some particular gland to elaborate the materials brought to it, or to do its share of excretion? If so, the mischief will immediately make itself felt in the circulation, and the conditions of the sufferer will become practically those of slow self-poisoning. So that on no hypothesis can we represent gout as an acquisition of the somatic cells exclusively.

It is the element of progressive heredity which makes the hypothesis of transmission of acquired characters an attractive one in a disease like gout. This element is, in the case of certain families, strongly marked. We even see children suffering from the disease. And bearing in mind what we know of its ætiology, we naturally say to ourselves, "It was not this child's fault that he was born gouty. 'The fathers must have eaten the sour grapes,' or in this case, perhaps, have drunk the sweet ones." But it needs but a moment's reflection to convince us that the element of progressive heredity, so far from being an anomaly, is deducible from the facts of the case. It is true that here we cannot directly apply the theory of natural selection. We are not now concerned with conditions of progress, but with those of regress. Nature selects the fittest. There is no reason why she should select the goutiest. The question we have to ask in disease is not whether Nature selects, but whether she summarily rejects. If she stepped in and exterminated the gouty, she would stop gout altogether, and with it the feature of progressive heredity. But there is no reason to suppose that, as a fact, she does anything of the kind. In the first place, gout is not a disease which seriously shortens life; in an advanced stage of civilization its existence is quite consistent, not merely with life, but with the active discharge of elaborate duties.

But there is another more important consideration. Strange as it may sound, there may be good reasons for supposing that Nature, so far from rejecting, might even select, the goutiest. For gout, like other diseases, is only one corner of a much wider question. Diseases have coincidents and relations which stretch beyond the bounds of pathology, and trespass upon biology. This, indeed, is a side of clinical study which has only comparatively recently received its proper recognition. In former days men contented themselves with observing the morbid symptoms of a gouty patient; they paid no regard to his other "points"—his nails, his teeth, his intellectual endowments. But it may often happen that morbid characters have their good affinities. This is probably the case in gout. We have heard it said, for example, by one of wide experience in this disease, "No gouty person is a fool"—a statement which derives some support from the number of eminent men who have been the subjects of this disease. It is often implied that in what is termed an "artificial" civilization natural selection ceases. Might we not, perhaps, say that it still proceeds, only upon a modified plan. The conditions of the competition for existence have altered. The fittest in one generation need not be the fittest of another. Thus, in a rude state of society, in which sustained physical strength is the one thing needful, the gouty man would have no chance. His enemies, however inferior they might be, would have nothing to do but to lay by for the next attack of gout, when they would easily kill him. In a more advanced state of society all this is changed. If the gouty man has talents, he probably has friends and money. There is no demand for sustained physical strength. If he has the gout he can be nursed. His gout may be even of advantage to him—he gets into the papers. So that, paradoxical as it may seem, Nature may even select the gouty, not for their gout, but for their biological equivalents.

We have shown then that Nature, so far from interfering to exterminate the gouty, might even select them. But a more plain and obvious reason exists for the progressiveness which we sometimes observe in gout. If gout be a modification of the system generally, if its progressive increase in the tissues of a gouty patient with increasing years is in some cases a matter of observation, it would only be reasonable to infer that the same is true of the reproductive cells. For, if they share in the degeneracy, why should they not share in the progressive tendency? In the light of this consideration we can explain a fact widely received among medical men—that the incidence of a gouty inheritance falls mainly upon the younger children. Since the reproductive cells as well as the somatic grow goutier and goutier as age advances, the later their separation occurs the more likely will they be to manifest gout.

(2) The second group includes cases in which there is an undoubted transmission of morbid characters, but where it is by no means certain that they were "acquired" in the sense under discussion. But even if they were, it does not seem that what was acquired is transmitted, but something broader, and more general. We shall take as examples two important diseases—phthisis and "new growths"—alluding briefly to the phenomena of "short sight."

Phthisis may be said to be in one sense, like gout, a disease acquired by civilized humanity. "The naked savage," writes Dr. Andrew in 1884,[2] "whatever ills he may have to bear, rarely reckons phthisis among them; with every addition to his clothing and the comfort of his tree or cave, proclivity to it increases,"—a statement which is fully borne out by what we know of the spread of phthisis in the Rocky Mountains and the islands of the Pacific. If we know less of the history of the rise and spread of phthisis than we do of gout, we have more definite conceptions regarding its pathology. At the present day that pathology may be said to have two sides. There is the side originated and elaborated by Koch—the demonstration of the constant presence of a vegetable parasite in the tissues in this disease. There is the chemico-physiological side. Before Pasteur's time, such terms as "medium," "soil," as applied to the human organism, were little more than metaphors, while such words as "constitution," "predisposition," had little more than a metaphysical value. At present, scores of workers are busily engaged in translating these terms from the language of metaphysics into their chemical and biological equivalents.

If, then, phthisis was originally acquired, what was it that was acquired? It would seem that we can take our choice between saying that the microbe was acquired, or a habit of body favouring its growth. Supposing, then, the acquisition to have been no more than the lodgment of a parasite in the tissues, can we suppose that it is the parasite which is transmitted? Our facts will hardly warrant such an assumption. How, for example, could we interpret such familiar incidents as the following? A mother, after giving birth to several children, who successively fall victims to phthisis in young adult life, is ultimately attacked herself by the same disease, at a date removed by an interval of several years from the birth of the last phthisical child. Here we should be driven to assume, not in the case of the mother alone, but in each of the several children, a long latent period, during which the parasites, though present in the tissues, made no sign. Such an assumption presents great difficulties. Again, the direct transmission of tuberculosis from a mother to her fœtus is admittedly rare, whereas on the supposed hypothesis we should expect to find it common.[1]

[1] *Brit. Med. Journ.*, 1884, 707

But if it is not the parasite that is transmitted, what *is* transmitted? We are driven back on the "other side" of the pathology of phthisis. But if we suppose that the transmission is not one of a parasite, but of a "diathesis," or "predisposition," then we desert the only standpoint from which there is any chance of proving that the disease was acquired in the sense under discussion. For what reasonable ground could we have for restricting this "predisposition" to the somatic cells alone, to the exclusion of the reproductive cells?

On the hypothesis that the thing transmitted is a "predisposition," we can, as in gout, explain the element of progressive heredity in phthisis. For, the admission of a morbid change once made, the difficulty is not so much to explain its progression as its arrest. In certain consumptive families we have in the limits of a single generation this morbid progress going on under our very eyes. It is the rule to find in such families, where several brothers and sisters are attacked, the younger fall victims at an earlier age than the elder, showing in this way their increasing liability. The explanation is probably identical with the one suggested in gout. The entire organism of the parent becomes more and more phthisically disposed—somatic and reproductive cells alike. The later the separation of the latter occurs, the more likely will they be to manifest phthisis.

The same line of argument is applicable to the facts of "short sight."[2] Short-sightedness is certainly hereditary—it runs in families—but that does not prove that we have in it an example of the transmission of acquired characters. For in the first place it would be very difficult to prove that the short sight was in the first instance acquired in the sense under discussion. While the progressiveness of the morbid character—which seems to support the theory—can be as well explained without it. For if there is no proof that the morbid character—the faulty build of the eye—is itself progressive, there is good reason to suppose that the habits of close attention which minister to the defect are so. In one generation we find a man simply tasking his eyes; his son works with a simple microscope; his grandson with an improved microscope.

I pass on to consider another group of pathological facts, of the highest importance and interest—new growths. The element of heredity doubtless obtains here as in the case of gout and phthisis. Thus the statistics of Sir J. Paget in this island, and those of Velpeau on the Continent, agree in showing that heredity can be traced in about one-third of the entire cases of cancer.[3] And among the benign tumours, as they are called, warts and exostoses are hereditary. Further, there is in some cases evidence of progressive heredity, the irregularity appearing in the children at an earlier age than it appeared previously in the parent. And we have here what might look at first sight more like a real transmission of acquired characters than anything we have yet dealt with. No one questions that something is transmitted. The theory of the local origin of the new growths is gaining ground everywhere, and might appear to carry the inference that they are acquired, and that no constitutional element is involved in them. Here, however, we must be on our guard against the fallaciousness of words. If by constitutional we mean something pervading the entire organism—a taint in the blood, and so forth—then there is little or no evidence to warrant our calling new growths constitutional. But if we mean, on the other hand, something which was represented in the original germ—an error in the original plan, not a supervening flaw—then there is nothing to encourage us in denying, and a good deal to warrant our asserting, their constitutional origin. However, such an admission is not necessary to our present purpose. Let us assume that they are acquired in the sense in which a scar is acquired. Is it a fact that what is acquired is transmitted? If so, we should look for identity in position and histological character in the thing transmitted. But on the whole neither of these conditions is fulfilled. Certainly they are not, in the case of cancer, as the analysis by Mr. Morrant Baker[1] of 103 of Sir J. Paget's cases clearly shows. The distribution of the cancers proper shows a variation within certain limits. There is a strong predilection for certain sites, but these sites are sufficiently numerous. Now, it often happens that, where several children inherit cancer from a parent, the growth appears in each case in a different site. Nor are the precise histological characters of the growth at all faithfully preserved in the course of transmission; while it has been often observed that on the bodies of cancerous people innocent growths exist as well.[2] So that the inheritance does not appear to be a liability to a peculiar modification in a certain part, but a tendency to one or more of a group of modifications in one of many possible sites.

Once more we find ourselves driven to a choice between two alternatives, either of which excludes the transmission of acquired characters. For if new growths are really acquired characters, then it is not exactly what is acquired that is transmitted, but something broader than it. If, on the other hand, they are only acquired in a more general sense, they fall outside the limits of Weismann's sense of the term "acquired character."

(3) There remain for our consideration the third, and, in one sense, the most important, group of pathological data—those which answer to the qualifications of acquired characters in Weismann's stricter usage of the term. Here, if anywhere, would be the ground in pathology to select for proving the theory of the transmission of acquired characters; but it must be confessed that this is just the region in which that theory receives the least support. This group of pathological facts embraces a number of accidental lesions, such as scars and mutilations, which are certainly acquired in the strictest sense of the word. But the evidence for the theory seems strong only in the dubious cases, weak in the unexceptionable ones. We have examples of mutilations practised for many centuries by entire races, without being transmitted in a single instance. Nor is it the experience of surgeons that scars and mutilations which are the results of operations are ever transmitted. On the other hand, we have histories of tailless cats and hornless cows. But here everything turns upon the comparative certainty with which we can prove that the initial lesion was really in the first instance acquired. Have we here to do with an accidental lesion or a deformity? A closer investigation has, in many instances, rendered the latter the more probable explanation of the two. For example, in the case of the tailless cats, closer research made it appear that the irregularity involved an abnormality affecting many of the lower vertebræ. In other cases, the abnormality in the child was so little like that in the parent, as to suggest that it was a merely accidental coincidence of two different lesions in one site.[3]

If we turn to the results of experimental research, we are confronted by more than one remarkable series of experiments, upon the bearing of which it is impossible as yet to pronounce decisively. The most notable work done in this direction is, perhaps, a series of experiments upon guinea-pigs, undertaken by Brown-Séquard, and repeated by Westphal.[4] They produced epilepsy in a number of these animals by various methods—section of the cord, section of different nerves, &c.—and observed subsequently that certain of the offspring were epileptic too.

But there are several reasons which prevent our accepting these results as decisive. The records of the experiments are said not to be very perfect. Then it is not contended that epilepsy was uniformly transmitted. What happened was that each member of the offspring presented some morbid symptom—usually some nervous trait, such as epilepsy or paralysis. So that the result of Brown-Séquard's experiments would rather seem to be this. By producing one morbid trait in the parents, he set up a liability to one of several in the offspring. By producing a single character, he set up a tendency. All this is of extreme importance, and it may well be that the future has much that is interesting to reveal in this direction. But, meanwhile, it cannot be said to lend very much direct support to the theory now under discussion.[1]

[4] See Brown-Séquard, "Researches on Epilepsy," Boston, 1857; Papers in *Journal de Physiologie de l'Homme*, tom. i. and iii., 1858, 1860; *Archives de physiologie normale et pathologique*, tom. i.–iv., 1868–1872. Ziegler and Nauwerck, vol. i. p. 390. See also Weismann on Brown-Séquard, pp. 81, 310, 313; translation, edited by Poulton.

Again, the choice of lesion in these experiments was a somewhat unhappy one. Epilepsy is a symptom which can be produced in a number of ways—its proximate cause, if there be a single one, we are not as yet in a position to formulate. Attempts in this direction usually go no further than a vigorous and often highly poetical description, in which metaphors drawn from the phenomena of electricity are liberally employed. It might have been more advantageous to have aimed at the production of less equivocal symptoms, whose pathology is less disputed—such, for example, as facial palsy.

Lastly, we cannot exclude from these experiments the possibility of the introduction into the system of chemical poisons or even parasites, as incidental results of the operations.

But this does not by any means exhaust our stock of instances. The pages of pathology furnish us with more than one group of important facts which satisfy all the conditions of acquired characters.

Chief among these stand those numerous modifications of various organs which we regard, and rightly regard, from a clinical point of view, as part of a given disease, but which might perhaps be more correctly described as secondary adjustments made by the organism to meet certain primary morbid changes induced in different organs by the disease itself. Such, for example, is hypertrophy of the heart consequent upon valvular disease. Such hypertrophy is or is not a morbid symptom according to the point of view we happen to take. From the clinical standpoint it may be conveniently treated as part of the disease. From the biological standpoint it is an effort on the part of the organism to adjust itself to altered conditions brought about by the disease. It is certainly an acquired character, in the strict sense of the term.

An illustration will make this plain. Rheumatic fever is an hereditary disease.[2] Inflammation of the valves of the heart is common in rheumatic fever, and hypertrophy of that organ often follows as a consequent of this. But who would reckon hypertrophy of the heart as forming part of a rheumatic inheritance? It is true, no doubt, that whoso is heir to a disease is heir by implication to all the biological incidents of that disease. But he is not heir to them for the same reason. The one belongs to him as the inheritor of a morbid tendency, the other as the possessor of an organism. Diabetes, again, is in some cases markedly hereditary. Secondary characters are acquired in the course of this disease also; such as hypertrophy of the bladder or stomach. But, however doomed from his cradle to diabetes a peason may be, he is not born with an hypertrophied bladder and stomach. We should think it absurd that such accommodations as these should be made before they were wanted. If, then, we are right in regarding these as really acquired characters—and it is difficult to see how we can avoid so doing—it seems that pathology has here afforded us a sort of crucial experiment. Of the morbid characters of which sundry diseases are constituted, some are inherited, some are acquired—the one are constantly transmitted, the others, so far as we know, never are.

But no one pretends that every disease is inherited. Consider, for example, such a disease as lead-poisoning. Here, there is not, obviously, any element of heredity. That two people are not equally liable may be true enough; that predisposing causes exist is doubtless the case; but that does not prove an element of heredity. Predispositions may be themselves acquired, as is the case in alcoholism. In such diseases as lead-poisoning, we rightly stress the importance of the environment, and minimize inherited tendencies. But such diseases will be of little use to us here, unless two conditions are complied with. The first is that they leave durable and definite lesions behind them; the second is that such lesions are not inconsistent with the procreation of children. Of such lesions the familiar "wrist drop" of lead-poisoning may be cited as a good example. It is often durable; in not a few cases it is not cured; it is not inconsistent with the procreation of children. But there is no evidence to show that this or kindred lesions are ever transmitted. Facial palsy would be another instance, this malady being often of considerable duration. This group of cases constitutes another piece of negative evidence, not so important as the last, because these cases are rarer, but still not unimportant.

It can hardly be disputed that these characters are acquired in the sense under discussion. There must have been frequent opportunities of transmission, but we have no evidence of anything of the kind.

The general conclusion we have arrived at in this paper is that pathology, so far from offering any support to the hypothesis of the transmission of acquired characters, pronounces against it. We have seen that it is possible to bring up a mass of evidence, which seems at first sight to favour that hypothesis. On further consideration, however, it becomes clear that only a small portion of that evidence can be allowed to "rank."

A considerable number of facts must be rejected, because though there can be no doubt that the morbid characters here present are both acquired and transmitted, they are not acquired in the sense under discussion—that is, by the somatic cells exclusively—but by the entire organism.

A considerable number of facts, again, meet with a like rejection, because there is no question that here certain morbid characters are transmitted, yet even supposing them to have been acquired, it does not appear that precisely what was acquired is transmitted, but something broader and more general.

A considerable number of facts remain, which may be allowed to "rank" as genuine instances of acquired characters. These, if the hypothesis be correct, should be transmitted. But of such transmission we find little or no trace.

If we begin with scars and mutilations, even if the facts are not all on one side, the balance of evidence is decidedly against the hypothesis. If we appeal to the results of experimental research, the question is more open; but if the hypothesis does not encounter quite so decided an opposition in this quarter, it can scarcely be said to derive much support there.

If we pass into the main region of pathology, we have to use some circumspection in looking about for instances which shall be genuine examples of acquired characters. That such instances really exist it has been our endeavour to show, notably in those secondary characters which organisms acquire by way of accommodating themselves to the effects produced by disease. So far from being rare or recondite, these constitute a group of familiar and well-ascertained facts. If transmission has not occurred, it cannot be for want of opportunity—there must have been scores of such opportunities. That it has not occurred, constitutes a piece of very important evidence against the hypothesis under discussion.

Henry J. Tylden.

A TRIP TO QUEENSLAND IN SEARCH OF CERATODUS.[1]

My main object in going to Queensland was to procure, if possible, the eggs of Ceratodus and the creature itself; secondly, I wanted to collect earthworms; and, thirdly, to see the country. In my main object I was quite unsuccessful, for the simple reason that this year Ceratodus did not lay its eggs till late on in November—two full months later than the time recorded by the only observer who had up till then procured them. University work forced me to return, not by any means empty-handed, but without the one thing which had tempted me to go north.

To save time, and avoid unpleasantness also, I went by train. It is a long weary ride across New South Wales, especially in warm weather. Unfortunately I left Sydney by the northern mail on Friday evening. There were very few carriages, and some of what there were were "engaged" for legislators who travelled home free and in ease whilst we who paid for our journey were huddled and crowded together. This discreditable state of affairs seems to be common at the close of each week during the sitting of Parliament in Sydney.

The journey north leads by the side of the Hawkesbury River, and after passing across the well-known bridge the train skirts the shores of what appears to be a succession of lakes. In reality, the winding river, shut in by wooded hills, expands every now and then into sheets of water, each of which in the gathering darkness seemed to be a little lake. About eleven o'clock you find yourself apparently running along through the streets of Newcastle, and stretching out eastwards see the long quays and open water leading out to the sea. The whole is brilliant with numberless electric lights, though you have an idea that in daylight coal dust would be a little too prominent. As it is, however, Newcastle is associated in one's mind with a series of flashing and twinkling lights prettily reflected in the water and with a very second-rate refreshment-room. Afer Newcastle you settle yourself down as comfortably as possible for a run northwards of 400 miles, through the night and greater part of the next day, to the Queensland border. You seem to get gradually more and more out of the world until at five o'clock next afternoon the train pulls up at the border station. By that time our number of passengers has been reduced to four. After looking about, a minute train, which at first sight you take for a toy, is descried at the end of the platform. Further searching shows a very narrow gauge line streaking away through the limestone hills northwards into Queensland. The original name of this border station was Wallangarra, but unfortunately this is now being changed to Jennings. It is a pity to lose the old native names and to substitute for them such ugly ones. One would have thought that a more effective plan of perpetuating the memory of legislators might have been devised.

---

[1] Paper read by Prof. W. Baldwin Spencer, before the Field Naturalists' Club at Victoria, on March 14. Reprinted from the *Victorian Naturalist* for June and July.

Small though the railway is, it is very comfortable and well managed, and all officials uniformly courteous. The carriages are like the insides of omnibuses, with a broad seat all round the windows. On express trains the last car is always for smokers, and has a little balcony on which you can sit out in the open air right at the end of the train, and hence shielded from wind and dust. This is a most excellent arrangement. From Wallangarra the train runs to Warwick, and then, across the uplands forming the Darling Downs with their wonderfully rich dark-red soil, on to Toowoomba. Here the line turns nearly due east and begins to climb gradually to the top of the Dividing Range close to the eastern escarpment of which Toowoomba lies. Suddenly you turn a corner, the upland country ends abruptly, and the train zig-zags rapidly down the face of the lofty escarpment which rises directly from the flat coastal district. The sun was setting just as we reached the crest, and in the brief twilight we had magnificent glimpses of the distant plains with the abrupt hill sides and deep gorges in the foreground. Close upon midnight Brisbane is reached.

A slight difficulty arose in Brisbane with regard to my small amount of collecting material, but on learning that it was simply intended for scientific purposes, the Customs officials at once courteously saved me all trouble by allowing it to enter free of duty. In fact my experience in Queensland was that I met with the greatest courtesy from all officials, and the greatest kindness from such friends and strangers as it was my good fortune to be brought into contact with—an experience common, I believe, to all visitors to the Northern colony.

From Brisbane the line is now continued through Maryborough on to Bundaberg at the mouth of the Burnett River.

About seventy-five miles north of Brisbane the vegetation changes almost suddenly, and the line runs across a belt of country, perhaps twenty miles wide, of a semi-tropical description. To this we will return presently; suffice it to say at present that the traveller finds himself suddenly surrounded by palms and pines and fig trees, and sees all the tree trunks covered with epiphytic ferns—with great masses especially of staghorn and bird-nest ferns, and with orchids from which hang down long clusters of yellow blossom.

This belt of vegetation stops as suddenly as it began some few miles south of Gympie—a well-known gold-mining town, which lies by the side of the Mary River, and where I had been told that Ceratodus was to be had in abundance. Here I determined to stay, and began at once to make inquiries. To my disappointment I found that no one at the hotel knew anything about the animal, but I wandered forth in quest of information. The river itself was dirty with the washings from the mines, and looked anything but promising; however, I made for some miserable huts on the outskirts occupied by Chinese, and after a little trouble found a fisherman amongst them. This individual was decidedly apathetic, but after some time said that he might or might not be able to catch me a few. Wandering along by the river I began to feel rather as if I were searching for a needle in a haystack. However, I learnt that the fish certainly were to be caught, though some few miles away, but that there was no chance whatever of getting assistance from any blacks, simply because there were not any in the neighbourhood, and at that time I thought their assistance indispensable. It was late in the afternoon and I wandered on by the river searching for planarians and earthworms. Amongst the former I secured two specimens of a beautiful new species, to which Dr. Dendy has given the name of *Geoplana regina*, and also specimens of the almost cosmopolitan form, *Bipalium kewense*, and of *Geoplana cærulea*, a form common in New South Wales, rare in Victoria, and very abundant indeed in Queensland. This was, I believe, the first time on which land planarians had been collected in Queensland—not that there was any difficulty in finding them, but that no one had taken the trouble to look before. Amongst earthworms, I collected for the first time for myself a true perichæte—that is, one in which the little setæ, or bristles, form a complete circle round each segment of the body. In all our Victorian forms, without exception, there is a break in the mid-dorsal and ventral lines where the setæ are absent. True perichætes do not appear to come further south than the north of New South Wales. Under the logs also were specimens of a common Queensland worm, *Cryptodrilus purpureus*; of a new species of perichæte worm, *P. gympiana*; together with three species of frogs—*Pseudophryne bibronii*, *P. australis*, and *Limnodynastes tasmaniensis*.

During the evening I had the opportunity of talking to one or two who were well acquainted with the country, and was strongly advised to go on without delay to the Burnett River. I determined that this would be the wisest course to adopt, and accordingly packed up next morning, and after an hour or two's stroll round Gympie, during which I did a large amount of log-rolling with but scanty success, owing to the extreme dryness of the country, once more took train northwards towards Maryborough. I spent the night at a little wayside inn, where considerable surprise was evinced at my putting in an appearance; however, a wandering lascar turned up, so that I was more or less kept in countenance, and together we had tea in what was presumably a combination kitchen and scullery. During two or three hours' collecting I met with nothing but gum trees, endless ants and scorpions, a few stray specimens of *Geoplana cærulea*, and one or two lizards and frogs. I somehow had the idea that north of Brisbane everything would be at least semi-tropical, and could not at first help feeling disappointed to find myself, except in the small district mentioned before, surrounded by little else but gum trees, without a trace of a palm or of anything which looked at all tropical. Eastern Gippsland was really richer in vegetation and more varied in form of animal life than the part of Queensland in which I spent most of my time. In fact, so far as my experience yet goes, Gippsland, as a general collecting ground, would be very hard to beat.

Early in the morning I started in a mixed train along a branch line leading inland for some fifty miles, till it stopped apparently nowhere in special, and not far from a fine mountainous bluff. The station is called Biggenden, and here we found coaches waiting for us. A Queensland coachdriver is a most marvellous man, both in the way in which he accepts with almost pleasure any amount of luggage, and in the way in which he stows it all on board. From Biggenden came a hot ride of about forty miles across uninteresting country. The only township we passed was a small place known as "The Shamrock," not far from the goldfield of Paradise. After changing horses we started off again, seeing nothing but gum trees and a few emus and kangaroos. Among the gums were what are locally known as blood gums, whose light-coloured trunks are covered with reddish blotches, due to the exhalation of kino; woollybutts, which for perhaps ten feet above the ground have the trunk somewhat like that of a stringybark, and above this are quite smooth and whitish; and a form of gum called brigalow. This grows in clumps, and differs from all the others in having its foliage comparatively dense, so that it affords a good deal of shade. The cattle congregate in the shade, and these dark patches give a curious and characteristic appearance to the landscape. Every now and then we came across a few birds, known as squat pigeons. These have the habit of squatting on the ground when approached, and, being of a brownish colour, are hard to see. Sometimes they can be knocked over by the whip of an experienced driver.

Late in the afternoon we mounted a slight ridge and came down through a gap into the wide Burnett Valley. On either side of this rise low hills, and through the middle flows the river with a broad channel, occupied chiefly—except during the flood season—by long, broad stretches of sand. A short ride brought us to Gayndah, a long, straggling township on the river banks, and here I took up my quarters in the comfortable

Club Hotel. At one time Gayndah was the centre of a wool-producing district, and bears evident signs of having seen a better day.

Intent on meeting with Ceratodus, I made my way to Mr. Thomas Illidge, the postmaster of Gayndah, to whom I had been recommended, and I gladly take this opportunity of expressing my thanks to him, not only for the valuable help and information which he gave me, but for many acts of kindness which added greatly to the pleasure of my stay in Gayndah. I may here also express my thanks to my friends, Dr. Cole and Messrs. Frank and Virgil Connelly, from whom—though a complete stranger—I received most valuable help. If a naturalist wishes to meet with genuine kindness and every possible assistance, I can warmly recommend Gayndah to him.

One of the first things I learnt was that Dr. Siemen, of the University of Jena, had recently come to the Burnett district for the purpose of securing the eggs of Ceratodus, and the various development stages of Platypus and Echidna; and not only this, but that he had secured the services of the available blacks. I must confess to a feeling of something like chagrin at having come so far to meet with, apparently, no chance of success in what was my main object.

After sleeping over my preliminary disappointment, I determined on carrying out the only plan possible, which was to obtain one or two boys accustomed to the river, and, with their help, to at any rate get Ceratodus, and, if possible, the eggs. It was now well on in September—the time at which Mr. Caldwell had found that the animal had laid eggs—so there was still hope that I might secure them. Perhaps it may be well here to state briefly the special interest which attaches to this particular form Ceratodus. As you all know, there are two groups of animals—the fishes and the amphibia—of which the first live in water, and breathe by means of gills, whilst the second either spend, as the newts do, their whole life in water, breathing by means of gills, or else, like the frogs, spend the early part of their life in water, breathing by gills, and then come out of the water and breathe by lungs just as reptiles and mammals do.

Now there is a very small group of animals known as the Dipnoi, which are, we may say, intermediate between the fishes and the amphibia. They are neither so lowly developed as the fishes, nor so highly developed as the amphibia—in fact, they may almost be described as "missing links" which still exist, and show us the way in which air-breathing were evolved from water-breathing animals. If we simply went by their external appearance we should class them amongst fishes, which they closely resemble in many respects. Now, fishes have what is known as a swim-bladder, which is merely a long hollow process developed from the œsophagus. This serves, probably, mainly as a float, and not at all for respiratory purposes; but in the small group, Dipnoi, of which Ceratodus is one, this same swim-bladder becomes modified to act as a lung. Not only this, but, whereas in fishes the impure blood which is carried from the body to the heart passes to the gills, is purified there and then goes straight to the body, in the Dipnoi part of the blood goes from the heart to the lung, and then is carried back again to a chamber in the heart specially developed for its reception. In fact, in the Dipnoi we can see some of the earliest stages in the evolution of important organs of the body as we now find them in all animals above fishes.

At the present time only three examples of the Dipnoi are known to exist in the world—one form, Lepidosiren, lives only in the Amazon; another, Protopterus, is only found in tropical Africa; and the third, Ceratodus, occurs only in the Burnett and Mary Rivers, in Queensland. In past times, however, Ceratodus lived in other parts, such as Europe, as its fossil remains testify; and in Australia Prof. Tate has recorded the presence of its teeth in the strata of the Lake Eyre basin. In fact, Ceratodus is one of those rare forms of which fossil remains were found and named before the living form was discovered.

The habits of Protopterus have been studied, and it is stated that during seasons of drought it makes a cocoon of mud for itself, and breathes by means of its lung. On account of this habit, these forms have often been called mud and lung fishes.

My main aim, then, was to find the eggs of the Ceratodus. From Mr. Caldwell's published notes, which are only too brief, I knew that it deposited them much like some amphibians, such as the Axolotl, do, on weeds, and that he had found them in September.

To return now to Gayndah. I purchased a tent and provisions, and having hired two boys accustomed to the river, started away to camp out some few miles up the Burnett. The country was very dry and sandy, with all the creeks empty of water. The outcropping rocks are granitic, with basalt capping the hills around, and the disintegration of the granite appears to give rise to a vast amount of sand. Along the river itself there is an alternation of large sandbanks, where the stream is shallow, and of long deep pools with great granite masses. The banks are bordered by bottle-brush trees (Callistemon), which at that time were crimson with flowers, and alive with thickheads. Leaving my stores to find their way to an appointed spot, I kept by the river bank on the look-out for weeds, for without these it was hopeless to set to work. After a short halt at a station close to Mt. Debatable, where the sociable wasp (*Polistes ferrugineus*) was busy making its nest in the verandah, I walked on until we were some six or seven miles out of Gayndah but there was not a trace of weed in the river. Close in to Gayndah, there was a small quantity, but where we expected to find a good supply there was none at all, owing apparently to heavy floods which in the last wet season had swept down the river. Accordingly we turned back and pitched our camp not far from Gayndah. It was evening by the time we were settled down, and too dark to see the eggs, so we lit a fire and fished. It was a lovely moonlight night and the coolness was delightful after the heat of the day. The river is full of fish, and we caught sand eels and mud eels, jew-fish, perch, and bream, but not a single Ceratodus—or, as they call it locally, salmon. Turtles kept rising to the surface and showing their black heads above the water, and every now and then when we sat still we could recognize a Platypus. In the morning I set to work to search over the weed. One of my boys stripped and went into the river for it, whilst I sat half in and half out of the water looking carefully over each piece. In the hot blazing sun this was not enjoyable, and after some hours' work, and not the slightest sign of an egg, and when the small patch of weed was pretty well exhausted, I sat down to think, and questioned my boys closely as to where there was more weed. A little way on the other side of Gayndah they told me there was a backwater usually full of weed. Why they had not told me of this before I could not imagine, and the remarks made probably conveyed this idea to them. However, we were close to the end of this weed, and as we had to get to some more, I sent one boy into Gayndah to procure help in removing our camp, for which, fortunately, I had made previous arrangements In the afternoon I finally exhausted the weed and myself with no result, and for a change set to work to turn over a few logs. Amongst planarians, *Geoplana cœrulea* and *variegata*; amongst earthworms, *Cryptodrilus purpureus*; amongst frogs, *Limnodynastes tasmaniensis* and *Hyperolia marmorata*; and amongst lizards, species of Pygopus, Hinulia, and Egernia, and a small mammal, a species of Antechinus, rewarded my efforts, but everything was too dry, though the season was early, for anything very much in the nature of worms. Along the river banks endless numbers of the beautiful butterfly *Danais erippus* attracted my attention. It was feeding on the plant (Lanthana) along with which it has been introduced. In the river itself was to be seen the curious water lizard *Physignathus lesueurii*, of which we caught a small specimen, and also the frog *Hyla lesueurii*, whilst the Callistemon trees contained plenty of a little green species of Hyla which the boys used as bait for fishing, and which appears to be new to science. I also caught this same frog on window panes at night in Gayndah, where, like a moth, it goes to the light. As the evening came on the mullet began to jump. They feed especially on a filamentous alga which grows in the water, and contains numerous crustaceans, especially a prawn-like form, for the sake of which they eat the alga. The latter is used as bait for them. At night we caught a large mud eel, five feet long, which we eagerly drew into land, thinking it to be a salmon. I tried sugaring the trees, but it was of no use, not even a single ant put in its appearance, and thus ended another day of hard work and disappointment.

In the morning I had my boys up by 4 a.m., and before six we were out of camp, and by nine o'clock had our tent pitched by the side of a backwater on the other side of Gayndah. This contained plenty of weed, and here I spent some days. We procured a long pole, with three prongs at the end, to pull the weed up with. We used to get a large bucketful at a time, and then go over it piece by piece. This process had to be conducted under a hot sun, and the result was that my arms became swollen to about double their natural size—so much, indeed, that I could not sleep with anything like comfort, since the slightest pressure woke me up. The final result was that I did not see the slightest trace of any Ceratodus eggs, though, had they been there, there is no doubt but that we should have found them. I then sent one of my boys down the river for some miles to see if there were any more weeds, but there were none to be seen. Just at this juncture I heard of some blacks, but on trying to secure them found that they were anticipating a "muster" on one of the neighbouring stations, and were not to be procured. Seeing no prospect of getting what I wanted, and being none the better for my exposure to the sun, I went into Gayndah.

Here I may, perhaps, say something as to some conclusions I had come to with regard to the habits of Ceratodus. With the exception of the brief account given by Mr. Caldwell as to the laying of its eggs on weed, and the curious amphibian-like embryos, we know little about the natural history of the animal. As before said, it is confined to two Queensland rivers—the Mary and the Burnett, and my experience is limited to the latter. Firstly, with regard to the animal's name. The Dipnoi have two popular names—"lung fishes" and "mud fishes"—the latter given to them because, in the case of Protopterus, the animal may live for a part of the year in mud. The Ceratodus is not known locally by either of these names; it is, however, sometimes called the "barramundi" and sometimes the "salmon." The first of these is, however, really that of a true osseous fish (*Osteoglossum leichardtii*), which lives chiefly in the Dawson and Fitzroy Rivers, further north than the Burnett. The second is a fanciful name, given on account of the very pink-coloured flesh of the animal. Beyond this there is no resemblance whatever between the real and the so-called Burnett "salmon." Mr. Saville Kent, in his report on fishes to the Queensland Government, states that Ceratodus is a valuable food fish. This is a curious mistake. Its flesh is very oily, coarse, and disagreeable, and it is but rarely eaten, and then only by Chinese and those who can afford nothing better. There is thus, I am thankful to feel, not much fear that so interesting an animal will become rapidly exterminated.

Now, as to its method of life. Ceratodus is a big fish, and may reach the length of six feet, and even more. I believe the largest ever caught weighed eighty-seven pounds. It is always to be met with in the deep pools, and not in the shallow waters, and it is important to notice that these pools are many of them of considerable extent, some more than a mile long. In the hottest summer they contain a good supply of water, and thus, though occasionally a Ceratodus may, of course, find its way into a shallow pool which gets dried up, normally no such thing happens, and the animal passes its whole life in water. The usual idea is that the lung is of service to the animal, as in the case of Protopterus, when the waters practically dry up. I very much doubt if Ceratodus ever makes for itself a mud cocoon, as Protopterus does. It may possibly, but very rarely, bury itself in mud, but the fishermen with whom I spoke, and who were perfectly well acquainted with the animal, knew nothing of its ever doing this. On the contrary, I fancy that the lung is of at least as great service to the beast during the wet weather as during the dry season—and probably even of greater.

Normally, then, we may say that Ceratodus never leaves the water. If by any chance it gets out of the water it is perfectly helpless. You may put one close to the edge and there it lies passively. Its weak limbs are quite incapable of sustaining the weight of the body. Nor can it live out of the water, unless kept constantly damp, for more than a very few hours—not, indeed, so long as the jew-fish from the same river. In the water, however, it constantly uses its lung. Sitting by the stream when all is quiet in the evening, you can hear a diminutive kind of spouting going on, the animal at intervals rising to the surface and expiring and inspiring air much as a minute whale might do. Out of the water, too, it does not open and shut its gill flaps like an ordinary fish, but they remain tightly shut, and the animal opens and closes its mouth, to all appearances breathing like one of the higher forms.

If we consider the environment of the Ceratodus we shall see that there are two special and constantly recurring conditions under which a lung would be useful to it.

In the wet season the tributary creeks, dry in summer, become transformed into roaring torrents, and when once you have seen the great sandbanks along the river bed and the dry sandy country through which the creeks pass, you can easily recognize what a vast quantity of sand must be brought down during the course often of a very few days, and how thick the water must become with fine particles. On the other hand, during the hot season there suddenly grow with enormous rapidity great quantities of water weeds. The river is then at its lowest and the decaying vegetable matter will often render the water foul. Under either of these conditions you can see that the possession of an organ enabling the animal to remain in its natural element and yet breathe air directly will be of great advantage to it. It is the shallower pools especially which become chocked with weeds, and since normally the Ceratodus lives in the deeper pools, in which is the purer water, it is, I think, very probable that the flood season, when the water is disagreeably full of sand and mud, is the time when the lung is of greatest service.

In Gayndah I learned that Dr. Siemen was camped out some forty miles up country, where the Auburn and Bowen Rivers join the Burnett, close to one another. Accordingly I made up my mind to go up the river, both to see him and to search for weed. The difficulty was how to get there. However, I met with a friend in the person of Mr. Bailey, proprietor of the Queensland Hotel, who, at considerable inconvenience to himself, promised to see me through the difficulty; and, taking one of my boys with me, we left Gayndah early one morning, before 4 a.m.

The country was extremely dry and sandy, with poor gum trees, and every now and then a patch of brigalow. By 10.30 we reached a wayside accommodation house, and then in the heat of the day we started off along a most miserable track across country as utterly uninteresting and monotonous as can well be imagined. We had two good dogs with us, and the only break in the monotony was when they put up a big "iguana." Most were much too quick for them, but one they got hold of, and it was wonderful to see how they stuck to him without getting within reach of his mouth. When all was over I slung him over a dead trunk, to get his head on the way back. However, when we came back he was not perfectly fresh, and was left behind. By 4 o'clock we had crossed the Bowen River and pitched our camp about a mile beyond. Then I walked on to Dr. Siemen's camp. My advent was announced by the yelping of sundry mongrels, the property of a small camp of blacks. On these animals I kept a sharp look-out. Dr. Siemen I found living in comparative luxury, and from him I received a most cordial welcome. We spent the evening most pleasantly talking over matters of common scientific interest. Three of his blacks came in with a few Echidnas. I learnt from him that he had been no more successful than myself in procuring Ceratodus eggs—that, in fact, they had not begun to spawn yet. Unlike myself, however, he was able to stay there until they did spawn, and most generously offered to procure certain material for me. There was a small amount of weed in the river but not a trace of an egg. On cutting open the body of a "salmon" I found the spawn inside, looking very similar, indeed, to that of a frog, each separate egg being black in colour at one pole. It was evidently not yet quite ripe for laying. The season when Mr. Caldwell got his eggs in September seems to have been an exceptional one as regards the temperature and amount of weed in the river. There had been no big flood for some time previously to his visit, so that the river was full of weed and everything was favourable for the depositing of spawn. This season, as luck would have it, the warm weather started rather late and the weeds had been largely washed away by heavy floods, the river at the end of September being comparatively high. I think it safe to say that, granted the presence of eggs, they could be got by "whites" just as well as by "blacks." Any collector going at the right time and not frightened of tiring and tedious work could get them for himself now that the manner of spawning has once been ascertained. Each egg, surrounded by a little gelatinous capsule, is laid on weed, but I think, from what I heard with regard to Mr. Caldwell's methods, that he found it necessary to spend a very considerable time in the neighbourhood of the river whilst the embryos were slowly developing, as they were not easily and safely carried about. The next day Dr. Siemen and I spent together with, I trust, mutual enjoyment—at all events, to myself it was one of the pleasantest days I spent in Queensland. I did a small amount of collecting, but it was far too dry and sandy to get anything in the way of worms. Down by the river I came across a black woman and pickaninny fishing, but they were frightened when I spoke to them, and fled. There were large numbers of *Danais erippus*, and of a beautiful species of Acræa with transparent wings. Late in the afternoon I attempted, but with not very great success, to photograph some blacks. One especially, named Frank, had his back scored with cicatrices in regular pattern. I spent the evening till 11 o'clock with Dr. Siemen, and said good-bye to him, wishing sincerely that he might be successful in his endeavours to secure what we were both in search of, and what it was perfectly evident that I myself could not obtain.

I may here say that Dr. Siemen had with him the best of the blacks who were with Mr. Caldwell, and who secured for the latter the eggs of Ceratodus. These blacks were fine and powerfully-built fellows; but here, as everywhere else, rum and disease are rapidly lessening their numbers.

On the way back our dogs started many big lizards, and it was amusing to see one of them hanging on to the tail of a large *Cyclodus gigas*, whose head and body were hidden in the hollow of a log. Jew lizards we met, as well as species of Hinulia and Liolepisma. We camped by the Burnett, some twenty miles out of Gayndah, and spent the evening fishing in a little backwater. There are two kinds of turtle in the river, the long-necked (*Chelodina longicollis*) and the short-necked (*Chelymis macquariensis*), and sometimes one is surprised at pulling out a turtle instead of a fish. Next day we made our way back into Gayndah, passing by large patches of grass trees in full flower, with swarms of the little black native bees hovering around them. Just as we were passing through a mob of travelling cattle our dogs started two kangaroo rats (*Bettongia*, sp.). There was a general scattering as the little animals, with the dogs in full chase, ran through the mob. After a short run one was caught, which had in its pouch a single small young one not more than 1½ inch long.

I stayed a few days in Gayndah, hoping to make a collection of earthworms, which up till then there had been very little chance of collecting. The name of the township will be well known to Australian etymologists, since it was here that Mr. Masters made a very fine collection; he was fortunate enough to have almost a year in the district, and thus secured forms at all seasons. About a mile behind the township is a large stretch of scrub, where I spent a considerable time, often accompanied by one or other of my friends—Messrs. Illidge, Cole, and Connelly—to whom I am indebted for help in the laborious task of digging out worms from dry ground. My favourite place was a large patch centering in a big bottle tree, *Sterculia quadrifida* (?). Here was an open space, lightly timbered with small trees of *Melia azedarach*, the light green foliage of which formed a strong contrast to the sombre foliage of the dense scrub all around. Besides eucalyptus and bottle trees, the scrub was made up of such trees and shrubs as *Geijera muelleri* and *salicifolia*, which were covered with small yellowish flowers, *Leptospermum lanigerum*, *Bursaria spinosa*, *Nephelium* (sp.), *Hovea longipes*, *Solanum stelligerum*, &c. I am indebted to the Baron von Mueller for his kindness in giving me the names of plants, to Mr. C. French for names of Coleoptera, to Mr. A. H. S. Lucas for names of amphibia and lizards. From the open spaces alleys lead away into the recesses of the scrub, and along these numbers of the beautiful *Danais erippus*, *Papilio erectheus*, and *Acrasea* (sp.) kept flying to and fro. Of birds, probably because I was not specially on the look-out for them, I saw very few.

The two most numerous forms of life were ants and millipedes. The moment you put anything which could serve as food for them on the ground, the former appeared as if by magic. Several times they spoilt butterflies just while I put them down on the ground and made a paper bag for them. They always bit off first the little knob at the end of the antenna. White ants of course abounded, and in the tree trunks were swarms of native bees. There were not as many logs to turn over as could have been wished for, and the ground also was rather too dry and sandy.

We began by digging around the base of the big bottle tree, and, after digging some time, came across some large worms, about two feet in length. These differ in habit from any others I have collected. The burrow runs down for perhaps two feet, and then opens into a small chamber. The head end of the worm lies usually a short distance up the burrow, whilst the greater part of its length is twisted into a knotted coil, and lies in the chamber which may also contain one or two smaller, immature forms, evidently the young of the larger ones. Under and in rotten logs you often meet with a shortish, stout worm, perhaps six or eight inches in length, which, at first sight, differs very much from the long one. Its body is stiff, and the surface comparatively dry, whilst the other is four or five times its length, the body soft and the surface always very slimy. The short one I met with all along the Burnett River, at Gympie and in the palm district between this and Brisbane, whilst Mr. D. Le Souëf collected it at Toowoomba. It is the *Cryptodrilus purpureus* of Michaelsen, and, much though the two differ in habits and appearance, the long one is at most a variety of the short, typical form. I only got it in this one spot. In the scrub were some four new species of the same genus, and three new species of a genus (Didymogaster) of which previously only one species had been described from New South Wales, by Mr. Fletcher. Of the typical Victorian genus, Megascolides, to which our large Gippsland earthworm belongs, I did not find any example in Gayndah, but the Perichætes were fairly well represented.

Most of the earthworms were secured under fallen logs and in rotten trunks of the bottle tree. In times of drought the latter are cut down, and, containing a great amount of moisture, are eaten readily by cattle.

The season was too early for beetles, but amongst others I secured specimens in the family Carabidæ of *Carenum deauratum* and *bonelli*, *Eutoma* (sp.), *Philoscaphus mastersii*, and *Homalosoma hercules*; and, in the Paussidæ, of *Arthropterus* (sp.). One species of the genus *Leptops*, in the Curculionidæ, simply swarmed on the bark of the bottle trees and some of the upturned logs in the more open parts were alive with the little red form, *Lemodes coccinea*.

A short time before leaving for Queensland I had been struck with the presence of curious laterally-placed segmental openings in a very large millipede from Fiji, which Mr. French had kindly forwarded to me. In the Gayndah scrub—where smaller, but still large, millipedes abounded—I was interested to find the meaning of these openings. Each one is connected with a gland, and, when irritated, the animal passes out a few drops of a most obnoxious fluid, of a red-brown colour, the function of which must be protective. Whilst on this subject, I may mention that one morning, when Mr. Frank Connelly and myself were digging for worms, we accidentally cut in two a cockroach. From between the segments in its back it poured forth a milky white fluid, possessing an odour so execrable and pungent that it drove us from the spot.

Under logs we found, also, of land planarians, *Geoplana cærulea* and *variegata*, and amongst Vertebrata, the frogs *Limnodynastes tasmaniensis*, which was common everywhere, and *Hyperolia marmorata*. Of lizards, we secured species of Phyllodactylus, Pygopus, Grammatophora, Hinulia, Liolepisma, and Egernia. Snakes were rare, only the genera Morelia, Furina, and Hoplocephalus being represented. Whilst in the scrub I did not see a single marsupial.

On the road from Biggenden to Gayndah I had been struck with the appearance of two small hillocks capped with basalt. The country all round was thinly wooded with nothing but gum trees, but just the tops of these two hillocks were rich with vegetation, though each was at most fifty yards in width. Dr. Cole, Mr. Illidge, and myself drove out to see if there were anything worth collecting. Unfortunately, since I had passed along the country had been fired and everything was as dry and parched as it well could be. However, just the very cap of the hills still formed a strong contrast to the surrounding country, and here we found growing—though nowhere else, apparently, except in these two very limited areas—*Damara robusta*, the Queensland Kauri, *Cupania xylocarpa*, *Micromelum pubescens*, *Carissa brownii*, *Citriobatus* (sp.), and amongst ferns a rich growth of *Polypodium* (sp.), and *Adriantum* (sp.). Animal life was almost absent. We disturbed three wallabies, but except these and a few millipedes and scorpions and endless ants, there was nothing to be seen.

My time was passing by rapidly, and though I would much have liked a few more days in the Gayndah scrub, it was a choice between this and two or three days in the palm district between Gympie and Brisbane. Regretfully I left Gayndah, and taking the coach back to Biggenden, found myself in the evening in Maryborough. In the morning I had about two hours to wander about. Close to the town were camped some blacks. It was curious to note how they had adapted themselves to their environment. They had made their "humpies" out of old sheets of corrugated iron. A semi-clothed native lying down in the shelter of a mia-mia made of English corrugated iron formed as incongruous a mixture as could well be imagined. Early in the afternoon I left the train at Cooran and took up my quarters in a delightful little wayside inn surrounded by ferns. On going up to the house I detected at once the genuine Lancashire dialect, and knew that the owner hailed from within ten miles of Manchester. I was accordingly made welcome, and wandered out to do a little collecting before evening came on. I found myself just on the northern border of the palm scrub which ran in a broad belt of about twenty miles width across the country from east to west, inland from the sea coast. The country was fairly hilly with a few isolated peaks standing out clearly. I was just at the base of one of these—Cooran—and to the south lay two more—Cooroora and Pimparan. South from these again the ridges increased in height, and then the country fell away into the slightly undulating plains which stretched eastwards towards Bribie Island and southwards to Brisbane. Some remarkable peaks, called the Glass Mountains, mark the southern end of the hilly district.

So far as animals are concerned, I was much disappointed with this palm scrub, but equally delighted with the richness of the vegetation.

Commencing first near to Cooran, I followed back the line and "log-rolled," finding a few worms and four land planarians (*Rhynchodemus obscurus*), a small, dark-coloured form, and *Geoplana cærulea* and *variegata*, together with specimens of a very small new white species, to which Dr. Dendy has given the name of *G. minor*. After long searching I came across *Peripatus leuckartii*, very dark purple in colour and evidently similar to the typical form and without the curious diamond-shaped markings characteristic of the Victorian form. Though searching hard, I only found nine specimens altogether, and all these close to Cooran. Most of my time was spent in this scrub at different parts, and usually in company with George Martin, the son of my Lancashire friends, who helped me very considerably in collecting. The scrub was very thick with vines and prickly lawyers and barristers and supplejack, making progress tedious, and there were comparatively few logs on the ground. What delighted me most were the ferns. The trunks of the pines and gums were often covered over with them and with orchids. High up were enormous clumps of the bird-nest fern (*Asplenium nidus*), and larger ones of the staghorn (*Acrostichum alcicorne*). Some of the latter measured fully twelve feet through, and from them hung down lovely pendant fronds of smaller ferns, especially of *Polypodium tenellum*, which is locally known as the feather fern. On the ground grew various species of Davallia, Adiantum, Pteris, Doodia, Aspidium, Polypodium, &c. Perhaps the most beautiful of all were the large and delicate fronds of *Adiantum formosum*. There were apparently three forms of palms—species of Ptychosperma, Livistona, and Kentia. The latter is very common, and usually known as the walking-stick palm. In the scrub were great pine trees, and under the bark stripped off from these, and lying about in large slabs, I expected to find any number of worms and insects, but was much disappointed. Millipedes and scorpions were there, and two large forms of land shells; but scarcely an insect to be seen, and not a planarian or peripatus. I got a few new species of earthworms, of which, again, the commonest form was *Cryptodrilus purpureus*; and in rotten logs, which, unfortunately, were few in number, were large forms of cockroaches. The earthworms formed the best part of my collection here, and comprised representatives of five genera—Perichæta, Megascolides (one species, the only one found), Cryptodrilus, Perissogaster, and Acanthodrilus. The latter is only recorded, as yet, from Northern Australia, where there are two species, and is characteristic of New Zealand. Perissogaster is peculiarly Australian and has only three species yet known. My specimens were obtained by digging on the banks of a creek at Cooran and were whitish in colour and about 1 to 1½ feet in length. The boys use them for fishing, quite unaware of their scientific value.

In Queensland, as in Victoria, I could very rarely, indeed, find traces of casts made by worms or of leaves dragged down into the burrows, and it would appear that here, as in Africa, the ants are of more use than the worms as agents in turning over the soil. Under the bark and logs were a few frogs—*Pseudophyrne bibronii* and *coriacea*, *Crinia signifera*, and a female specimen of *Cryptotis brevis*. In certain spots there were great numbers of trap-door spiders. Some of the tubes, which led for about 2-4 inches down into the ground, were an inch in diameter. The top of the tube, with its semi-circular trap-door, projects slightly above the surface.

One of the most striking features of the scrub were the epiphytic orchids, of which, owing to its size and large pendant masses of yellow-brown flowers, *Cymbidium canaliculatum* was the most noticeable. In parts the ground was crimson with the fallen berries of a species of Eugenia: we cut one down about sixty feet high, laden with fruit, which has a tart taste, and from its colour and size has caused the tree to be known as the native cherry. Another Eugenia has a large purple fruit, and is hence known as the native plum. High up, some fifty feet above ground, we saw hanging down clusters of light brown fruit. Luckily there was a hanging vine close at hand, and up this George Martin went like a monkey. The fruit belonged to the tree *Dysoxylon rufum*, and each was covered over with innumerable minute stiff hairs, which pierced the skin in hundreds. Other plants we noticed were the wistaria, which here grows wild, *Dracæna angustifolia*, and one which Baron von Mueller has marked as rare—*Rhipogonum elseyanum*. Two dangerous ones are common, one with large bright green leaves and succulent sheathing stalks, which is locally known as the "Congey Boy"—this is eaten greedily by the native turkeys, but has the effect of making a man's tongue swell to an enormous extent; the other is the stinging tree, *Urtica gigas*—the sting of this is extremely painful, and seems to prove fatal to horses, driving them rapidly frantic.

Close by the base of Mount Cooroora, a beautiful specimen of *Macrozamia denisoni* in fruit was growing, and on Mount Cooran the rock on the western side was completely overgrown with staghorn and bird-nest ferns and with an orchid, *Dendrobium* (sp.), with beautiful clusters of delicate white flowers, amongst which trailed *Kennedya rubicunda*, its bright red blossoms contrasting strongly with the pure white of the orchids.

My last day I spent at the Glass Mountains—curious cone-like basaltic structures rising abruptly from almost flat country. The day was oppressively hot, making it no small exertion to even turn over a log, and as the sun went down a heavy storm came up, and from the train I caught my last glimpses of this delightful district lit up by almost incessant flashes of brilliant lightning.

SCIENTIFIC SERIALS.

The American Journal of Science, July.—The change of heat conductivity on passing isothermally from solid to liquid, by C. Barus. The method employed was a modification of Weber's, who placed a thin, wide, plane-parallel plate or layer of the substance to be examined between and in close contact with two thick plates of copper. The system was first heated so as to be at a given temperature throughout. It was then suddenly and permanently cooled at the lower surface, and the time-rate at which heat travelled from the top plate to the bottom plate, through the intervening layer, was measured by a thermo-couple. From these data the absolute thermal conductivity of the layer may be computed, the constants of the system being known. In the experiments discussed, the liquid was thymol, which can be kept either solid or liquid between 0° and 50° C. This was heated above its melting point, and introduced through a central hole in the upper plate; it was then allowed to cool down until undercooled. The temperature was regulated by enclosing the whole apparatus in a sheet-iron jacket, through which water was kept circulating. The lower plate could be cooled by flushing it with water from below. The difference of temperature of the plates was measured by means of a copper german-silver couple. The liquid was solidified by introducing a crystal through the central hole. The results obtained gave for the absolute conductivity of thymol in g/cs:

Solid thymol at 12°, $k = 359 \times 10^{-6}$
Liquid thymol at 13°, $k = 313 \times 10^{-6}$

The thermometric conductivity was found to be—

For solid thymol at 12°, $= 1077 \times 10^{-6}$
For liquid thymol at 13°, $= 691 \times 10^{-6}$

—On polybasite and tennantite from the Mollie Gibson mine in Aspen, Colorado: by S. L. Penfield and Stanley H. Pearce. Large quantities of polybasite or "brittle silver" have been mined nearly free from gangue, assaying from 10,000 to 16,000 ounces of silver to the ton. Tennantite, arsenical tetrahedrite, or "grey copper," was found in smaller quantities, containing about fourteen ounces of silver. The rich ore occurs between a hanging wall of black carbonaceous shale and a foot wall of grey magnesian limestone, which is probably of lower carboniferous age. The ore is richest and most abundant immediately under the black shales. Other minerals observed are native silver, argentite, galena, sphalerite, siderite, barite, and calcite.—Post-Laramie deposits of Colorado, by Whitman Cross. This paper, published by permission of the director of the United States Geological Survey, deals with some beds occurring between the lowest eocene and the marine cretaceous deposits, which have hitherto been classed with the Laramie formation of the Rocky Mountains. The age of the firm grey sandstones and coal-measures of the latter has long been doubtful, and they have been variously described as secondary and tertiary. In the Denver region, two beds are found overlying the Laramie unconformably, the one consisting of a pebbly conglomerate, the other of débris of andesitic lavas; they have been termed the Denver and Arapahoe formations respectively. Their equivalents have been found in various other parts of Colorado. When, after the continental elevation which caused the retreat of the Laramie seas, sedimentation began again, it was in comparatively small seas or lakes. Succeeding the first period of lake-beds came a time of great volcanic outbursts over a large area. The length of geologic time occupied may not have been very great, but the extent of country in which eruptions occurred at this time, and the great variety of lavas found in the Denver and Middle Park regions, argue for the decided importance of the event as a dynamic manifestation. The writer wishes to advocate the restriction of the term Laramie, in accordance with its original definition, to the series of conformable beds succeeding the marine Montana cretaceous, and the grouping of the post-Laramie lake beds in another series, to which a comprehensive name shall eventually be given.—On the alkali-metal pentahalides, by H. L. Wells and H. L. Wheeler. With their crystallography, by S. L. Penfield. An account of the preparation and properties of compounds of the formulæ CsI_5, $CsBr_5$, $CsCl.Cl_3I$, $RbCl.Cl_3I$, $KCl.Cl_3I$, $NaCl.Cl_3I.2H_2O$, $LiCl.Cl_3I.4H_2O$. The first is triclinic, the third, fourth, and fifth are monoclinic, and the Na salt is orthorhombic.—Fossils in the "archæan" rocks of Central Piedmont, Virginia, by N. H. Darton. Remains of crinoids belonging to the upper Ordovician fauna were found in the roofing slate of Arvon, Buckingham County, Virginia, which has hitherto been classified as Huronian.—Notes on the Cambrian rocks of Virginia and the southern Appalachians, by Chas. D. Walcott. It is shown that towards the close of middle Cambrian time, and during upper Cambrian time, there was a decided continental movement, resulting in the depression of the interior continental plateau, and that this was accompanied by the formation of conglomerates of the older Cambrian rocks in the valley of the St. Lawrence, and by a great deposition of sediments of later Cambrian time in the southern Appalachian region.—Synthesis of the minerals crocoite and phœnicochroite, by C. Ludeking, Ph.D. This was accomplished by exposing for several months to the air a solution of lead chromate in caustic potash in a flat dish. A mixture of the two kinds of crystals resulted, which could be easily sorted by means of a pincette.—A hint with respect to the origin of terraces in glaciated regions, by Ralph S. Tarr. Tracing a resemblance between the flood terraces of the Colorado in Texas, and the glacial terraces of the Connecticut.—Occurrence of a quartz boulder in the Sharon coal of north-eastern Ohio, by E. Orton.—A method of increasing the range of the capillary electrometer, by John Whitmore. An account of some experiments performed in the Sloane Physical Laboratory of Yale College, with a view towards improving the mercury and sulphuric acid electrometer as constructed by Lippmann and Pratt. Instead of having alternate bubbles of the two liquids, the surface of the mercury exposed to oxygen polarization was increased by blowing the tube into bulbs at the junction. A series of bulbs was blown, spaced at equal intervals along a capillary tube, the diameter of the bulbs being two centimetres, that of the tube 0·6 mm.; then the tube was so bent, that the whole contained as many U-shaped parts as there were cells. One arm of each U was provided with a bulb, which was situated at a distance of two-thirds the height of the U from the base. The apparatus was filled by connecting it with an aspirator, and drawing in sufficient mercury to half fill each bulb, after which dilute sulphuric acid was added by the same means. Platinum electrodes were used, and the variations in the height of the mercury columns produced by the E.M.F. examined, were read by means of a cathetometer. The deflection produced by a standard Clark cell was 3·20 mm. The range of the instrument is limited by the E.M.F. required to produce continuous electrolysis, but it was found that it could be considerably increased by using a larger number of cells in series. It is possible to determine with this electrometer the E.M.F. of a cell correctly to 0·001 of a volt.

SOCIETIES AND ACADEMIES.

LONDON.

Chemical Society, June 16.—Prof. A. Crum Brown, F.R.S., President, in the chair.—The following papers were read:—Contributions to an international system of nomenclature. The nomenclature of cycloids, by H. E. Armstrong. An account was given of the proceedings at the recent Conference on Chemical Nomenclature at Geneva, and attention was directed to the significance of the chief resolutions. A report of the conclusions arrived at by the Conference has already appeared in NATURE (this vol., p. 56).—The production of pyridine derivatives from the lactone of triacetic acid, by N. Collie and W. S. Myers. The product of the interaction of ammonia and triacetic lactone is most probably an αγ-dihydroxy-α-picoline. By the action of phosphorus oxychloride on this substance a compound possessing all the properties of a dichloropicoline is obtained, and on passing this, together with hydrogen, over heated zinc-dust, α-picoline boiling at 128–129° is produced. The melting points of the platini- and auri-chlorides, obtained from the synthetical alkaloid, agree with those given by the corresponding compounds prepared from pure α-picoline which was made by heating pyridine methiodide.—The fermentation of arabinose by *Bacillus ethaceticus*, by P. F. Frankland and J. MacGregor. The products are qualitatively the same as were obtained in the fermentations of glycerol by the same organism, consisting of ethyl alcohol, acetic acid, carbon dioxide, hydrogen, and traces of succinic acid, together with another acid which was not identified. When the fermentation is conducted in a closed space a notable proportion of formic acid also occurs among the products. In this case the products are formed approximately in the proportions—$3C_2H_6O$, $3C_2H_4O_2$, $4CH_2O_2$, the formic acid as well as the carbon dioxide and hydrogen found being all collected together as formic acid in this statement. In the fermentations conducted in flasks plugged only with cotton wool, on the other hand, the alcohol and acetic acid were formed in the proportion $2C_2H_6O$, $3C_2H_4O_2$. It appears, therefore, that in the fermentation of arabinose by *Bacillus ethaceticus*, the proportion of acetic acid to alcohol is greater than in that of dextrose, and still greater than in the cases of mannitol and glycerol, but less than in that of glyceric acid.—Resolution of lactic acid into its optically active components, by T. Purdie and J. W. Walker. The authors have resolves ordinary inactive lactic acid into lævo- and dextro-lactic acid by taking advantage of the different solubilities of the strychnine salts of these components. Strychnine lævolactate is considerably less soluble in water than the dextrolactate, although both salts may be crystallised. By fractional crystallization of the mixed salts and subsequent removal of the strychnine from the crystals and mother liquor, by means of ammonia or barium hydrate, solutions were obtained which were respectively dextro- and lævo-gyrate. The dextrolactate yielded a zinc dextrolactate having the same composition and solubility as zinc sarcolactate. A well-defined dextro zinc ammonium salt of the composition $Zn.NH_4\,(C_3H_5O_3)_3,\ 2H_2O$ having the specific rotatory power $[\alpha]_D = +6{\cdot}49$ (approx.) was prepared. The dextrogyrate salts yield a lævogyrate acid, which, like sarcolactic acid, gives an oppositely active anhydride. The quantities of oppositely active acids separated from each other by means of the strychnine salts possessed equal amounts of optical activity. Fermentation lactic acid is thus shown by analysis to consist of two oppositely active isomeric acids, one of which is identical with dextrogyrate sarcolactic acid, and the other with the lævogyrate acid prepared by Schardinger by the bacterial decomposition of cane sugar.—A new method for determining the number of NH_2 groups in certain organic bases, by R. Meldola and E. M. Hawkins. In order to ascertain the number of NH_2 groups present in certain organic bases the authors propose to form the azoimides; on analysis of these substances, the number of amidogen groups which have been diazotized, can be determined. For example, paradiamidoazobenzene $(NH_2.\,C_6H_4)_2N_2$ was diazotized and converted into tetrazoperbromide in the usual way. This latter substance, by the action of ammonia, yields lustrous silvery scales of the azoimide.

The analysis of this substance proves without doubt that two amidogen groups were present in the original base.—The existence of two acetaldoximes. Second notice, by W. R. Dunstan and T. S. Dymond. The authors have more fully investigated the change undergone by acetaldoxime on heating (see NATURE, this vol., p. 94). The pure crystals melt at 46·5°; after heating at 100° for a few minutes the liquid does not begin to crystallize until 13°. On separating the crystals now formed, and cooling the liquid still more a further crop of crystals is obtained. Each of these separations is found to melt at 46·5°. Acetaldoxime therefore exists in two modifications, one, the crystalline form melting at 46·5°, and the other, a liquid form which the authors find cannot be obtained in a pure state, as when it approaches purity it partially reverts to the modification melting at 46·5°.—The dissociation constants of organic acids, by J. Walker. The author has measured the dissociation constants of a number of organic acids and ethereal salts.—Note on the preparation of alkyl iodides, by J. Walker. The author has devised a method for conveniently and rapidly preparing considerable quantities of methyl and ethyl iodides. The apparatus employed consists of a modified fat extraction apparatus, by means of which the iodine is dissolved by the condensed alcohol, and runs into a vessel containing the phosphorus and alcohol. The method gives a good yield, and may be applied to the preparation of higher iodides.—An examination of the products obtained by the dry distillation of bran with lime. Preliminary communication, by W. F. Laycock and F. Klingemann. On distilling a mixture of bran and quick-lime, a black oil, floating on an aqueous solution is obtained. The aqueous solution smells of herring brine, contains much ammonia, and on boiling evolves inflammable gases. The oil is evidently a complex mixture, and has not yet been separated into its constituents.—The atomic weight of palladium, by G. H. Bailey and T. Lamb.—The action of sulphuryl chloride on acetorthotoluidide and acetparatoluidide, by W. P. Wynne.

PARIS.

Academy of Sciences, July 18.—M. d'Abbadie in the chair.—On a slight additive correction which may have to be applied to the heights of water indicated by sea-gauges, when the swelling or chopping agitation of the sea reaches a great intensity: case of a choppy sea, by M. J. Boussinesq. In this second case the correction is much smaller than in the former, amounting to not more than 0·1 mm. in an extreme case.—Preparation and properties of proto-iodide of carbon, by M. Henri Moissan. If an exhausted sealed tube containing crystals of the tetra-iodide of carbon be heated in an oil bath to 120°, iodine is liberated and condenses in the cooler portion of the tube, while less volatile crystals of the proto-iodide of carbon are produced, corresponding to the formula C_2I_4. To obtain greater quantities, the tetra-iodide is reduced by silver powder. The substance obtained presents itself in beautiful pale yellow crystals of density 4·38, fusing at 185°, and volatile without decomposition below their point of fusion. By slow volatilization in a vacuum at a temperature between 100° and 120°, transparent crystals are produced, some of which form highly refracting hexagonal tablets. The proto-iodide is very soluble in carbon bisulphide, tetrachloride, and ordinary ether, which, by cooling, gives good crystals. The new compound is very stable, being not oxidized by potassium permanganate, and boiling chromic and nitric acids.—On one of the reactions of spermine, by M. Duclaux.—On a fossil baboon of the quaternary phosphorites of Algeria, *Macacus trarensis*, by M. A. Pomel.—Project of meteorological observatories on the Atlantic Ocean by Albert I., Prince of Monaco. A proposal to establish a station on the Azores as soon as the projected cable is laid, and also on Madeira, the Canaries, Bermuda, and the Peak of Teneriffe. It is expected that the prediction of cyclones will be much facilitated, and Monaco is suggested as a centre for the collection and distribution of the information obtained.—On the specific heat and the latent heat of fusion of aluminium, by M. J. Pionchon. The total quantity of heat required to raise 1 gr. of aluminium from 0° to its fusing point, 625°, is 239·4. The latent heat of fusion is very large, being equal to that of water, viz., 80 cal.—On the measurement of the dielectric constant, by M. A. Perot. The further value obtained for glass was 2·39, which, obtained by means of a glass prism weighing 65 kg., agrees very well with that obtained from very rapid oscillations. The values obtained by these two methods, being unaffected by residual charges, are more reliable than those derived from the static, the attraction, and the ballistic galvanometer methods.—On the principle of maximum work, by M. H. Le Chatelier. An examination of the bearing of certain thermodynamic laws on Berthelot's principle, showing that the contradiction between them is only apparent.—On a basic nitrate of calcium, by M. A. Werner.—On the efflorescence of sulphate of copper and some other metallic sulphates, by MM. H. Baubigny and E. Pechard.—On the decomposition of the basic nitrates by water, by MM. G. Rousseau and G. Tite.—On phosphopalladic combinations, by M. E. Fink.—On the mechanical contrast between the radical cyanogen and the chloroid elements, by M. G. Hinrichs.—The influence of the substitution of the methyl group for one benzene hydrogen on the properties of orthotoluidine, by M. A. Rosenstiehl.—On the instability of the carboxyl in the phenol acids, by M. P. Cazeneuve.—On preserved ferruginous mineral waters, by M. J. Riban.—On a new leucomaine, by M. A. B. Griffiths.—Effects of sudden release on animals placed in compressed air, by M. G. Philippon. It was found that although rabbits subjected to a pressure of six or eight atmospheres were unaffected if the pressure was gradually released, a sudden expansion was followed by almost instantaneous death. The cause of death appears to be the mechanical expansion of the gas contained in the vessels, which, in the case of gradual release, is eliminated by the lungs in a few minutes.—On the immediate reparation of losses of intra-osseous substances, with the aid of aseptic bodies, by MM. S. Duplay and M. Cazin.—The coxal gland of the scorpion and its morphological relations to the excretory glands of the Crustacea, by M. Paul Marchal.—The avalanche of the Têtes-Rousses. Catastrophe of St. Gervais-les-Bains (Haute-Savoie), by M. F. A. Forel.—On certain forms of filling-up observed in some lakes of the Pyrenees, by M. Emile Belloc.

COAL-TAR COLOURING-MATTERS.

Tabellarische Uebersicht der künstlichen organischen Farbstoffe. Von Gustav Schultz und Paul Julius. R. Gaertner's Verlagsbuchhandlung, Hermann Heyfelder. (Berlin, 1891.)

DR. SCHULTZ is well known to "tar chemists" as the author of "Die Chemie des Steinkohlentheers," the most exhaustive work on coal-tar products which has hitherto been written, and of which the first edition appeared in 1882, and the second, enlarged to two thick volumes, in 1887–1890. His colleague Dr. Julius is the author of a useful little work on the same subject published in 1887. The volume before us is a remarkable production from every point of view, and well worthy of the reputation of the two authors who have collaborated in its production. Although nothing more than a tabulated catalogue of coal-tar colouring-matters, as it professes to be, the work is in reality a complete index to the literature of this rapidly growing branch of industry; complete, that is to say, to the date of its publication; but development is taking place even now at such a pace that a single year has sufficed to render a supplement necessary, and many of the most recently added colouring-matters are not included in the lists. The first edition of the "Tabellarische Uebersicht" was published in 1888 and contained 278 colouring-matters; the present edition contains 392 colouring-matters—a fact which speaks for itself with respect to the progress of chemical discovery in this direction. The volume is dedicated to the late Prof. von Hofmann, whose labours in this field in the early days of the industry will render his name inseparable from that band of pioneers who were the first to penetrate into the new regions opened up by the discovery of mauve by Dr. W. H. Perkin in 1856.

The volume of tables under consideration has become indispensable to every chemist engaged in the manufacture of, or in any way interested in, the coal-tar colouring-matters. To the general chemist it will be a matter of wonder that from three to four hundred distinct compounds, for the most part of known constitution, definite in character, often beautiful in crystalline form and appearance, and, in short, all well-characterised "chemical individuals," should be turned out of factories by hundredweights and tons for consumption in the tinctorial industries.

The authors group the colouring-matters under sixteen headings:—Nitro-derivatives, Azoxy-compounds, Hydrazones, Azo-compounds, Nitroso-compounds (quinone-oximes), Oxyketones, Diphenyl-methane derivatives, Triphenyl methane derivatives, Indophenols, Oxazines and Thiazines, Azines, Artificial Indigo, Quinoline colouring-matters, Acridine colouring-matters, Thiobenzenyl derivatives, and colouring-matters of unknown constitution. The tables are arranged in eight columns, the first containing the commercial name of the colouring-matter, the second its scientific name, the third its empirical formula, the fourth its constitutional formula, the fifth its mode of preparation, the sixth its date of discovery, the seventh the name of the discoverer and literary references, and the eighth its general properties and mode of application. From this analysis it will be seen that the work is, as we have stated, a complete epitome of the coal-tar colour industry. Its value as a work of reference for technologists will be appreciated by all who may have occasion to consult it; our own experience has been that the many thousand references to chemical literature, patents, and periodicals, are given with an accuracy that leaves nothing to be desired. One special feature to which attention must be directed is that the compounds tabulated are or have been actual articles of commerce. If the colouring-matter has been superseded, as must inevitably be the case with the progress of discovery, the authors announce the fact by stating *nicht mehr im Handel*. Thus the reader is made acquainted with the actual state of the industry, and the student with these tables at hand will be prevented from becoming a prey to the snares of the compilers of examinational text-books, who are only too frequently quite out of touch with the technology of their subject. Writers of this class are apt to set forth lists of compounds which are worthless to the manufacturer, and which are of value only to the examiner in technology by enabling him at once to separate the sheep from the goats among his candidates—to distinguish the students whose knowledge has been derived solely from books from those who are actually engaged in the factory.

One very forcible truth which is brought home on running the eye down the seventh column of the tables before us is the great preponderance of references to patents, chiefly German. It is evident that the chemist who wishes to keep abreast of modern discovery can no longer afford to neglect the literature of the Patent Office. Many discoveries of the greatest scientific importance are buried in these specifications, and it is long before they find their way into the text-books. This, so far as we are concerned, is much to be regretted, for, in the first place, the working chemist is already painfully overburdened with literature, and in the next place the statements in specifications require very judicious sifting before they can be admitted as part of scientific knowledge. The student who is not familiar with the coal-tar colour industry would be hopelessly entangled among the mazes of patent literature were it not for such practical guides as Drs. Schultz and Julius, who have evidently used the greatest judgment in giving their references. In other words, the patents quoted have reference to the production of compounds which are, or were, manufactured, and the reader who consults their work may feel assured that the "bogus" or "fishing" patent, which may be so innocently swallowed by the unwary, will not be obtruded on his notice.

So far as English technologists are concerned, it is to be regretted that such an overwhelming majority of German patents have to be referred to. This, of course, is only to be expected, when we consider the extraordinary activity which the Germans have displayed in the development of the industry of which the foundations were laid in this country about thirty or forty years ago. But the technological student is thereby placed at a disadvantage because German patents are not very readily obtainable. It is true that all capital discoveries are also patented in this country, but, on the other hand, there are many important chemical processes discovered and patented on the Continent which are not filed in our Patent Office, and which are so long in finding their way into the current literature that they are apt to be overlooked. Chemists who have occasion to consult the admirable series of tables by Schultz and Julius cannot but look with admiration—even if tinged with envy—at the brilliant series of discoveries which have emanated from the laboratories of German universities, technical schools, and factories. This is the fruit of technical education in the true sense ; no system of cramming for an examination, no method of orthodox "test-tubing," not even the "recreative institute" line of technical training, which is so much in vogue at the present time, will enable us to recover our lost position in this or in any other branch of chemical technology.

R. MELDOLA.

RAM BRAMHA SÁNYÁL ON THE MANAGEMENT OF ANIMALS IN CAPTIVITY.

A Handbook on the Management of Animals in Captivity in Lower Bengal. By Ram Bramha Sányál, Superintendent of the Zoological Garden, Calcutta. (Calcutta, 1892.)

CONSIDERING the number of zoological gardens in Europe, and their long establishment, it is singular that it should have been left to the superintendent of a zoological garden at Calcutta, and to a native of India withal, to produce the first practical handbook on the management of animals in captivity. The author, who, we believe, is a member of the "Brahma Somaj," and one of the very few natives of British India that have exhibited any taste for natural history, has been for some years superintendent of the Zoological Garden at Calcutta, an excellent institution mainly kept up by the Government of Bengal, but under the control of a committee of the subscribers. This committee, at the suggestion of Sir Steuart Bayley, the Lieutenant-Governor of Bengal, came to the conclusion that, after thirteen years' experience of the management of animals, it might be possible to produce a handbook on the subject which "would be of interest to the scientific world," and at the same time "of great use to nobles and other persons who, on a smaller scale, keep a collection of animals in captivity."

Such was the origin of the present volume, which has been prepared by Babu Ram Bramha Sányál, on a plan drawn up by a sub-committee appointed for the purpose, and has been supervised by Mr. C. E. Buckland, C.S., who was at one time honorary secretary to the Calcutta Garden, and is now a member of the Council of the Zoological Society of London. It is certainly a work of considerable interest. In the first place it has the merit of giving us a complete classified list of all the mammals and birds that have been kept alive in the Calcutta Garden. These are, of course, mostly species of British India—241 of the class of mammals, and 402 birds—but there are a good many exotic forms among the birds. In the second place large numbers of notes on the treatment of the animals in health and in sickness, on their length of life in captivity, and generally on their habits as observed in confinement are introduced, which, although in some cases of an apparently trifling nature, are well worthy of study by those who are engaged in the custody of living animals. It is evident that the author has kept a regular journal, and has recorded his experiences very minutely. In a case of a fight between a lioness and a tiger, which were by some accident allowed to pass into the same compartment of the Carnivora house, the tiger was completely victorious and killed the lioness. The longest period during which a tiger has lived in the Calcutta Gardens is fourteen years. It is curious that the Lesser Fruit-bat of Bengal (*Cynopterus marginatus*) "does not appear to bear captivity well." A nearly allied African species (*C. collaris*) has completely established itself in our Regent's Park Garden, and has bred abundantly for the last twenty years. On January 30, 1889, a young rhinoceros was born in the Calcutta Gardens, "the second recorded instance" of this mammal having bred in captivity. Interesting details are given of this event. The parents were a male Sumatran rhinoceros and a female of the northern form of the same species, which has been separated as *Rhinoceros lasiotis*. The highest bliss of these animals, as the Babu points out, is to "lie undisturbed in a muddy hollow," besmeared with liquid dirt.

In 1886 the Calcutta Garden obtained from Dar-es-Salam, in Eastern Africa, a young hippopotamus, but it did not live for more than eighteen months. Probably its voyage from Zanzibar to Calcutta "in an ordinary box without water" materially affected its health, as the hippopotamus, if properly treated, does exceedingly well in captivity.

The authorities of the Calcutta Garden have not yet succeeded in keeping the pangolin alive for any lengthened period. The same has been the case in our Zoological Gardens, where, although several examples of this Edentate have been received, not one has survived many weeks. This is curious, as both the American ant-eater (*Myzmecophaga*) and the African ant-bear (*Orycteropus*) maintain excellent health in captivity. It is suggested that the difficulty of obtaining a supply of their proper food—the *termites*—is the cause of this failure. At the same time, when supplies of this insect have been placed within reach the Pangolin has been "known to take no notice of them." We cannot therefore suppose that the true solution of this difficulty has yet been hit upon. It may be stated that in a similar manner ant-eaters kept in this country will not eat ants, but thoroughly enjoy raw meat when minced up small in a sausage machine.

The second part of the handbook contains a list of the birds exhibited in the Calcutta Garden, and corresponding observations upon them, but naturally there is not so much to be said on this branch of the subject. Among the more interesting species of this order we notice the fine large Laughing-thrush of the Himalayas (*Garrulax leucolophus*), the gold-fronted chloropsis (*Chloropsis aurifrons*), several sorts of drongo (*Dicruridæ*), Gould's ouzel (*Merula gouldi*), and the pheasant-tailed jacana (*Hydrophasianus chirurgus*), all birds which are rarely, if ever, seen in European aviaries. On the whole we must allow that this volume is a remarkable production, considering the circumstances under which it has been prepared, and that its author deserves great credit for the pains bestowed on its composition, and for much valuable information contained in it.

OUR BOOK SHELF.

In Starry Realms. By Sir Robert S. Ball, D.Sc., LL.D., F.R.S. (London: Isbister and Co., 1892.)

THIS is another striking example of Sir Robert Ball's skill in popularizing the most fascinating of the sciences. Though the same story has been to a large extent told by him before, there are several new features which prevent the least suspicion of staleness. The author is perhaps most interesting in his homely illustrations of astronomical dimensions. Among these are the disc of the moon projected on the map of Europe, and three lunar craters similarly compared with the map of England. The history of a falling star, as told by a particularly intelligent meteorite, is also worth special notice.

The two final chapters consist of "An Astronomer's Thoughts about Krakatoa," and "Darwinism in its Relation to other Branches of Science." The former is a popular account of the Report of the Krakatoa Committee of the Royal Society. The moral of the last chapter is that the scientific method of Darwin is closely related to that employed in astronomy. "Astronomers were the first evolutionists: they had sketched out a majestic scheme of evolution for the whole solar system, and now they are rejoiced to find that the great doctrine of Evolution has received an extension to the whole domain of organic life by the splendid genius of Darwin" (p. 349). We can confidently recommend the book to all classes of readers. Those who are already familiar with the subject will find much to delight them.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Basset's Physical Optics.

I DESIRE to make a few remarks on Prof. Schuster's review of my treatise on physical optics.

The sentence in the preface to which he refers is not perhaps very happily arranged, and might be amended as follows:—

"I have a profound distrust of arguments based upon vague and obscure general reasoning instead of upon rigorous mathematical analysis." This, however, is a small matter; what I wished to protest against was, the practice which has crept into more than one recent work, of slurring over an investigation by means of a page or two of general talk, instead of writing out a careful mathematical demonstration; or at any rate making a serious attempt to grapple with mathematical difficulties, and trying to arrive at a definite result.

I fully admit, that when a subject is in a state of growth it is often impossible to dispense with hypothesis. But whenever this is necessary, the hypothesis should be expressed in clear and definite language; the evidence and arguments for and against the hypothesis should be properly marshalled and discussed; the reader should be plainly informed that the proposition which forms the basis of the investigation is a hypothesis and not an established fact, and that consequently further research may show that the hypothesis must either be abandoned or modified. When an investigation is conducted on these lines, all obscurity and vagueness will be avoided; for the reader will be thereby enabled to clearly understand the exact nature of the assumptions which are made, and will be able to discriminate between those portions of the investigation which consist of hypothesis, and those which constitute results deduced from hypothesis by the aid of mathematical analysis.

The dangerous character of arguments based upon general reasoning is well illustrated by the theory of the deformation of thin elastic plates and shells. When a thin shell is deformed by means of bodily forces, and stresses applied to its edges, the effect produced is extension, change of curvature, and torsion; and it might be argued from this, that the potential energy due to deformation is a homogeneous quadratic function of the quantities by which extension, change of curvature, and torsion are specified. But if the expressions for the potential energy of a cylindrical or of a spherical shell be examined (Phil. Trans. 1890, pp. 443, 467), it will be found that they contain certain terms which involve the *differential coefficients* of quantities by which extension is specified.

With regard to the concluding portion of the review, I must point out that one of the difficulties with which the author of an advanced treatise is confronted is *where to draw the line.* Upon this subject there is necessarily room for a wide difference of opinion. As my object was to write a book on physical optics, I considered that the reader might properly be expected to obtain his information respecting the various theories of the electromagnetic field, from the treatises and original memoirs on that subject; and for that reason I abstained from discussing purely electromagnetic theories, further than was necessary for the explanation of optical phenomena. A. B. BASSET.

July 25.

Causes of the Deformation of the Earth's Crust.

THE communication from E. Reyer in NATURE of July 7 (p. 224) "On the Causes of the Deformation of the Earth's Crust" is interesting from several points of view. It is an indication that the theory which looks upon mountain ranges as the effects of the earth's contraction does not satisfy the conditions of the geologist.

It is welcome to me individually as in the main accepting the principles of which I happen to be the exponent, and have systematized in the "Origin of Mountain Ranges," published in 1886. It is, however, the addition to this theory explaining the folding of strata by what Mr. Reyer aptly calls "gliding" that calls for examination. It is shown very clearly by experiment and otherwise that under certain conditions strata, when they reach a certain degree of inclination on the flanks of a mountain chain during elevation, must glide downwards by gravitation and produce folds and disturbances towards the lowlands. We have only to consider the effects of land-slides such as occur in the chalk districts in the south of England, and their effects on the shore deposits, to admit the truth of this. This aspect of the problem, though always present, has grown on me since my work was published, and I have little doubt that the "foot-hills" usually formed of the newer strata which flank most great mountain ranges are to a considerable extent due to gravitation and "gliding." I may point to the foot-hills of the Canadian Rockies and of the Himálayas as illustrations. The cases of folded lying upon undisturbed strata mentioned by Reyer are, as he clearly shows, explanatory on this view, but not by general contraction.

There are no doubt other effects traceable to the gravitation of masses of the earth's crust during elevation such as the lateral spreading of the plastic cores of mountain ranges in fan-like form, and the consequent shouldering of the strata on either side intensifying the effects of the folding of the strata by thermal expansion, as explained in the "Origin of Mountain Ranges."

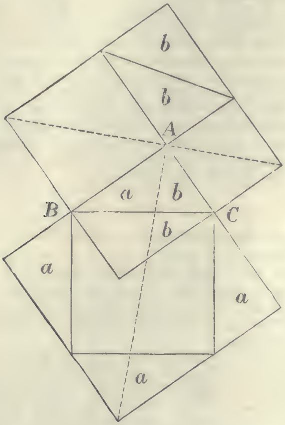
I cannot, however, follow Mr. Reyer if he considers "gliding" an explanation of all folding. I am not sure that this is his meaning, though the last paragraph would seem to bear such an interpretation. It seems obvious to me, to mention only one of numerous examples, viz., the folds of Jurassic strata caught up in the gneiss of the Central Alps, as shown in Heim's section, reproduced in "Prestwich's Geology," and in plate xiv., "Origin of Mountain Ranges."

While looking upon "gliding" as only a partial explanation of folding, I welcome Mr. Reyer's fresh and vigorous treatment of the important problem of the causes of the deformation of the earth's crust. It is evidence that geologists and physicists are now allowing their minds to play freely round the subject of the orogenic changes of the earth's crust, and of the growth of philosophical conceptions on the geological evolution of our planet.

Park Corner, Blundellsands, T. MELLARD READE.
July 11.

An Obvious Demonstration of the 47th Proposition of Euclid.

SOME years ago in trying for a simpler demonstration of this theorem I worked out the following. Its extreme simplicity suggested that it could scarcely be original; but as some years have elapsed, and as none of my friends have seen it elsewhere, I send it to you as possibly of interest to some and perhaps of use where practical geometry is being taught. It is evident that the two larger squares are equal, the side of each being equal to the sum of the sides AB, AC of the triangle ABC. It is also clear that the four triangles marked "*a*" are equal to one another. Again, the four triangles marked "*b*" are equal to one another, and to the four triangles marked "*a*."



Hence taking four times the triangle "*a*" from one of the large squares and four times triangle "*b*" from the other, there remain in the one case the square on BC, and in the other case the squares on AB and AC, and these remainders are equal. Therefore the square on the hypothenuse is equal to the sum of the squares on the other two sides.

Canterbury College, New Zealand University,
June 15.

[The principle of the above solution is not new. A proof, by dissection, depending on it is given in several text-books. The novelty of it consists in the position of the squares by means of which the truth of the property is seen in one figure.]

Musical Sand. Lava in the Bournemouth Drift.

IN reference to the note in NATURE (July 21) respecting musical sand in Australia, permit me to say that the subject has long since received attention there. I am away from references at present, but I should think it must be over two years since Mr. Sidney Olliff kindly sent me samples from Botany Bay. The samples sent were enclosed in small canvas bags, and, though there was probably not more than half-an-ounce of each, they were very musical on reaching me. For purity and musical effect, the Botany Bay samples were more like the Eigg sand than any other kinds I had previously examined.

During the last five years I have been collecting the various kinds of rock found in the Bournemouth high-level gravels (Codrington). A section has lately been exposed at the head of Alum Chine. Here a bed of angular and sub-angular flint gravel 5 ft. (varying) in thickness rests on the Bagshots, and is covered by sand, humus, and peat. At the base of the gravel bed I disinterred (on the 17th inst.) a small piece of vesicular lava, much decomposed in places, but retaining more than sufficient of its original structure for purposes of identification.

The specimen will be sliced for the microscope; in the meantime I draw attention to it because it is, to my knowledge, the first specimen of vesicular lava that has been found in these gravels. CECIL CARUS-WILSON.

Oxford, July 27.

The Flora and Fauna of Bromley.

THE Bromley Naturalists' Society have recently appointed a Special Committee to draw up lists of the flora and fauna of the Bromley Union District. This district comprises the parishes of Beckenham, Bromley, Chelsfield, Chislehurst, Cudham, Down, Farnborough, Foots Cray, Hayes, Keston, Knockholt, Mottingham, North Cray, Orpington, St. Mary Cray, St. Paul's Cray, and West Wickham.

I am desired to ask you to allow me to state that the Special Committee will be glad to receive from your readers any information which in their opinion might be of service to the Committee. J. FRENCH.

Hon. Sec. Special Committee.

99, Widmore-road, Bromley, Kent, July 27.

THE BRITISH ASSOCIATION.

EDINBURGH.

AN Edinburgh meeting of the British Association seems almost a home meeting. At every turn we are reminded of some of those who bore their part in founding and building up the Parliament of Science. Sir David Brewster meets us in the University quadrangle. The chair now set apart for the President of Section A was occupied for many years by James David Forbes, while for one brief year Natural History in Edinburgh was identified with Edward Forbes, to whom the Association owes, among many greater things, the evolution of the Red Lion. Viewed through the vista of years, the intellectual life of Edinburgh seems to have been marked by the combination of the love of science and letters with the full enjoyment of social intercourse, and we have before us such evidence of the persistence of this trait as bodes well for the success of the meeting.

The reception rooms are in keeping with the dignity of the Association, and afford every facility for the transaction of business. The programme of local arrangements which has been put in the hands of members indicates ample variety of occupation for hours of leisure. This pamphlet is of convenient size and easy of reference. In one point of detail it is worthy of remark; its maps do not require to be unfolded; these are two, one showing clearly, although on a small scale, Edinburgh and its suburbs, and the other giving, on a large scale, the part of the city which will be most frequently traversed by visitors. The Excursion Handbook has evidently been compiled with much care, and it will prove an interesting and artistic souvenir of the meeting.

Sir Archibald Geikie, the President of the Association, was President of the Geological section at the 1871 Edinburgh meeting. His address, suggested by the centenary of Hutton's "Theory of the Earth," deals with a subject in which Scottish geologists have ever been well to the front. The last decade of geological work in Scotland has done much to unlock the secrets of rock structure, and there could be no more fit exponent of the results than the president.

In the section programmes we hear promise of many welcome papers and several important discussions; in Section A, on Monday, the question of a National Physical Laboratory will be dealt with; while Tuesday will be devoted to a discussion on electrical units, in this Prof. von Helmholtz is expected to take part; Section B and D will consider bacteriology, with special reference to Brewing; Section D, "Fisheries"; Section F, "Old Age Pensions." In Section C, the feature of the meeting is likely to be the review of recent work in the geology of Scotland, and the presence of a considerable number of foreign geologists is sure to lead to interesting discussions. The Prince of Monaco will give in Section E the results of his observations on ocean currents. Section G will this year devote some attention to the subject on which there is much difference of opinion, the education of engineers.

Inaugural Address by Sir Archibald Geikie, LL.D., D.Sc., For.Sec.R.S., F.R.S.E., F.G.S., Director-General of the Geological Survey of the United Kingdom, President.

In its beneficent progress through these islands the British Association for the Advancement of Science now for the fourth time receives a welcome in this ancient capital. Once again, under the shadow of these antique towers, crowded memories of a romantic past fill our thoughts. The stormy annals of Scotland seem to move in procession before our eyes as we walk these streets, whose names and traditions have been made familiar to the civilized world by the genius of literature. At every turn, too, we are reminded, by the monuments which a grateful city has erected, that for many generations the pursuits which we are now assembled to foster have had here their congenial home. Literature, philosophy, science, have each in turn been guided by the influence of the great masters who have lived here, and whose renown is the brightest gem in the chaplet around the brow of this "Queen of the North."

Lingering for a moment over these local associations, we shall find a peculiar appropriateness in the time of this renewed visit of the Association to Edinburgh. A hundred years ago a remarkable group of men was discussing here the great problem of the history of the earth. James Hutton, after many years of travel and reflection, had communicated to the Royal Society of this city, in the year 1785, the first outlines of his famous "Theory of the Earth." Among those with whom he took counsel in the elaboration of his doctrines were Black, the illustrious discoverer of "fixed air" and "latent heat"; Clerk, the sagacious inventor of the system of breaking the enemy's line in naval tactics; Hall, whose fertile ingenuity devised the first system of experiments in illustration of the structure and origin of rocks; and Playfair, through whose sympathetic enthusiasm and literary skill Hutton's views came ultimately to be understood and appreciated by the world at large. With these friends, so well able to comprehend and criticize his efforts to pierce the veil that shrouded the history of this globe, he paced the streets amid which we are now gathered together; with them he sought the crags and ravines around us, wherein Nature has laid open so many impressive records of her past; with them he sallied forth on those memorable expeditions to distant parts of Scotland, whence he returned laden with treasures from a field of observation which, though now so familiar, was then almost untrodden. The centenary of Hutton's "Theory of the Earth" is an event in the annals of science which seems most fittingly celebrated by a meeting of the British Association in Edinburgh.

In choosing from among the many subjects which might properly engage your attention on the present occasion, I have thought that it would not be inappropriate nor uninteresting to consider the more salient features of that "Theory," and to mark how much in certain departments of inquiry has sprung from the fruitful teaching of its author and his associates.

It was a fundamental doctrine of Hutton and his school that this globe has not always worn the aspect which it bears at present; that, on the contrary, proofs may everywhere be culled that the land which we now see has been formed out of the wreck of an older land. Among these proofs the most obvious are supplied by some of the more familiar kinds of rock, which teach us that, though they are now portions of the dry land, they were originally sheets of gravel, sand, and mud, which had been worn from the face of long-vanished continents, and after being spread out over the floor of the sea, were consolidated into compact stone, and were finally broken up and raised once more to form part of the dry land. This cycle of change involved two great systems of natural processes. On the one hand, men were taught that by the action of running water the materials of the solid land are in a state of continual decay and transport to the ocean. On the other hand, the ocean-floor is liable from time to time to be upheaved by some stupendous internal force akin to that which gives rise to the volcano and the earthquake. Hutton further perceived that, not only had the consolidated materials been disrupted and elevated, but that masses of molten rock had been thrust upward among them, and had cooled and crystallized in large bodies of granite and other eruptive rocks which form so prominent a feature on the earth's surface.

It was a special characteristic of this philosophical system that it sought in the changes now in progress on the earth's surface an explanation of those which occurred in older times. Its founder refused to invent causes or modes of operation, for those with which he was familiar seemed to him adequate to solve the problems with which he attempted to deal. Nowhere was the profoundness of his insight more astonishing than in the clear, definite way in which he proclaimed and reiterated his doctrine, that every part of the surface of the continents, from mountain-top to sea-shore, is continually undergoing decay, and is thus slowly travelling to the sea. He saw that no sooner will the sea-floor be elevated into new land than it must necessarily become a prey to this universal and unceasing degradation. He perceived that, as the transport of disintegrated material is carried on chiefly by running water, rivers must slowly dig out for themselves the channels in which they flow, and thus that a system of valleys, radiating from the water-parting of a country, must necessarily result from the descent of the streams from the mountain crests to the sea. He discerned that this ceaseless and widespread decay would eventually lead to the entire demolition of the dry land; but he contended that from time to time this catastrophe is prevented by the operation of the underground forces, whereby new continents are upheaved from the bed of the ocean. And thus in his system a due proportion is maintained between land and water, and the condition of the earth as a habitable globe is preserved.

A theory of the earth so simple in outline, so bold in conception, so full of suggestion, and resting on so broad a base of observation and reflection, ought, we might think, to have commanded at once the attention of men of science, even if it did not immediately awaken the interest of the outside world; but, as Playfair sorrowfully admitted, it attracted notice only very slowly, and several years elapsed before any one showed himself publicly concerned about it, either as an enemy or a friend. Some of its earliest critics assailed it for what they asserted to be its irreligious tendency—an accusation which Hutton repudiated with much warmth. The sneer levelled by Cowper a few years earlier at all inquiries into the history of the universe was perfectly natural and intelligible from that poet's point of view. There was then a widespread belief that this world came into existence some six thousand years ago, and that any attempt greatly to increase that antiquity was meant as a blow to the authority of Holy Writ. So far, however, from aiming at the overthrow of orthodox beliefs, Hutton evidently regarded his "Theory" as an important contribution in aid of natural religion. He dwelt with unfeigned pleasure on the multitude of proofs which he was able to accumulate of an orderly design in the operations of nature, decay and renovation being so nicely balanced as to maintain the habitable condition of the planet; but as he refused to admit the predominance of violent action in terrestrial changes, and on the contrary contended for the efficacy of the quiet, continuous processes which we can even now see at work around us, he was constrained to require an unlimited duration of past time for the production of those revolutions of which he perceived such clear and abundant proofs in the crust of the earth. The general public, however, failed to comprehend that the doctrine of the high antiquity of the globe was not inconsistent with the comparatively recent appearance of man—a distinction which seems so obvious now.

Hutton died in 1797, beloved and regretted by the circle of friends who had learnt to appreciate his estimable character and to admire his genius, but with little recognition from the world at large. Men knew not then that a great master had passed away from their midst, who had laid broad and deep the foundations of a new science; that his name would become a household word in after generations, and that pilgrims would come from distant lands to visit the scenes from which he drew his inspiration.

Many years might have elapsed before Hutton's teaching met with wide acceptance, had its recognition depended solely on the writings of the philosopher himself. For, despite his firm grasp of general principles and his mastery of the minutest details, he had acquired a literary style which, it must be admitted, was singularly unattractive. Fortunately for his fame, as well as for the cause of science, his devoted friend and disciple, Playfair, at once set himself to draw up an exposition of Hutton's views. After five years of labour on this task there appeared the classic "Illustrations of the Huttonian Theory," a work which for luminous treatment and graceful diction stands still without a rival in English geological literature. Though professing merely to set forth his friend's doctrines, Playfair's treatise was in many respects an original contribution to science of the highest value. It placed for the first time in the clearest light the whole philosophy of Hutton regarding the history of the earth, and enforced it with a wealth of reasoning and copiousness of illustration which obtained for it a wide appreciation. From long converse with Hutton, and from profound reflection himself, Playfair gained such a comprehension of the whole subject that, discarding the non-essential parts of his master's teaching, he was able to give so lucid and accurate an exposition of the general scheme of Nature's operations on the surface of the globe, that with only slight corrections and expansions his treatise may serve as a text-book to-day. In some respects, indeed, his volume was long in advance of its time. Only, for example, within the present generation has the truth of his teaching in regard to the origin of valleys been generally admitted.

Various causes contributed to retard the progress of the Huttonian doctrines. Especially potent was the influence of the teaching of Werner, who, though he perceived that a definite order of sequence could be recognized among the materials of the earth's crust, had formed singularly narrow conceptions of the great processes whereby that crust has been built up. His enthusiasm, however, fired his disciples with the zeal of proselytes, and they spread themselves over Europe to preach everywhere the artificial system which they had learnt in Saxony. By a curious fate Edinburgh became one of the great headquarters of Wernerism. The friends and followers of Hutton found themselves attacked in their own city by zealots who, proud of superior mineralogical acquirements, turned their most cherished ideas upside down and assailed them in the uncouth jargon of Freiberg. Inasmuch as subterranean heat had been invoked by Hutton as a force largely instrumental in consolidating and upheaving the ancient sediments that now form so great a part of the dry land, his followers were nicknamed Plutonists. On the other hand, as the agency of water was almost alone admitted by Werner, who believed the rocks of the earth's crust to have been chiefly chemical precipitates from a primeval universal ocean, those who adopted his views received the equally descriptive name of Neptunists. The battle of these two contending schools raged fiercely here for some years, and though mainly from the youth, zeal, and energy of Jameson, and the influence which his position as Professor in the University gave him, the Wernerian doctrines continued to hold their place, they were eventually abandoned even by Jameson himself, and the debt due to the memory of Hutton and Playfair was tardily acknowledged.

The pursuits and the quarrels of philosophers have from early times been a favourite subject of merriment to the outside world. Such a feud as that between the Plutonists and Neptunists would be sure to furnish abundant matter for the gratification of this propensity. Turning over the pages of Kay's "Portraits," where so much that was distinctive of Edinburgh's society a hundred years ago is embalmed, we find Hutton's personal peculiarities and pursuits touched off in good-humoured caricature. In one plate he stands with arms folded and hammer in hand, meditating on the face of a cliff, from which rocky prominences in shape of human faces, perhaps grotesque likenesses of his scientific opponents, grin at him. In another engraving he sits in conclave with his friend Black, possibly arranging for that famous banquet of garden-snails which the two worthies had persuaded themselves to look upon as a strangely neglected form of human food. More than a generation later, when the Huttonists and Wernerists were at the height of their antagonism, the humorous side of the controversy did not escape the notice of the author of "Waverley," who, you will remember, when he makes Meg Dods recount the various kinds of wise folk brought by Lady Penelope Pennfeather from Edinburgh to St. Ronan's Well, does not forget to include those who "rin uphill and down dale, knapping the chucky-stanes to pieces wi' hammers, like sae mony road-makers run daft, to see how the warld was made."

Among the names of the friends and followers of Hutton there is one which on this occasion deserves to be held in especial honour, that of Sir James Hall, of Dunglass. Having accompanied Hutton in some of his excursions, and having discussed with him the problems presented by the rocks of Scotland, Hall was familiar with the views of his master, and was able to supply him with fresh illustrations of them from different parts of the country. Gifted with remarkable originality and ingenuity, he soon perceived that some of the questions involved in the theory of the earth could probably be solved by direct physical experiment. Hutton, however, mistrusted any attempt "to judge of the great operations of Nature by merely kindling a fire and looking into the bottom of a little crucible." Out of deference to this prejudice Hall delayed to carry out his intention during Hutton's lifetime. But afterwards he instituted a remarkable series of researches which are memorable in the history of science as the first methodical endeavour to test the value of geological speculation by an appeal to actual experiment. The Neptunists, in ridiculing the Huttonian doctrine that basalt and similar rocks had once been molten, asserted that, had such been their origin, these masses would now be found in the condition of glass or slag. Hall, however, triumphantly vindicated his friend's view by proving that basalt could be fused, and thereafter by slow cooling could be made to resume a stony texture. Again, Hutton had asserted that under the vast pressures which must be effective deep within the earth's crust, chemical reactions must be powerfully influenced, and that under such conditions even limestone may conceivably be melted without losing its carbonic acid. Various specious arguments have been adduced against this proposition, but by an ingeniously devised series of experiments, Hall succeeded in converting limestone under great pressure into a kind of marble, and even fused it, and found that it then acted vigorously on other rocks. These admirable researches, which laid the foundations of experimental geology, constitute not the least memorable of the services rendered by the Huttonian school to the progress of science.

Clear as was the insight and sagacious the inferences of these great masters in regard to the history of the globe, their vision was necessarily limited by the comparatively narrow range of ascertained fact which up to their time had been established. They taught men to recognize that the present world is built of the ruins of an earlier one, and they explained with admirable perspicacity the operation of the processes whereby the degradation and renovation of land are brought about. But they never dreamed that a long and orderly series of such successive destructions and renewals had taken place, and had left their records in the crust of the earth. They never imagined that from these records it would be possible to establish a determinate chronology that could be read everywhere, and applied to the elucidation of the remotest quarter of the globe. It was by the memorable observations and generalizations of William Smith that this vast extension of our knowledge of the past history of the earth become possible. While the Scottish philosophers were building up their theory here, Smith was quietly ascertaining by extended journeys that the stratified rocks of the West of England occur in a definite sequence, and that each well-marked group of them can be discriminated from the others and identified across the country by means of its enclosed organic remains. It is nearly a hundred years since he made known his views, so that by a curious coincidence we may fitly celebrate on this occasion the centenary of William Smith as well as that of James Hutton. No single discovery has ever had a more momentous and far-reaching influence on the progress of a science than that law of organic succession which Smith established. At first it served merely to determine the order of the stratified rocks of England. But it soon proved to possess a world-wide value, for it was found to furnish the key to the structure of the whole stratified crust of the earth. It showed that within that crust lie the chronicles of a long history of plant and animal life upon this planet, it supplied the means of arranging the materials for this history in true chronological sequence, and it thus opened out a magnificent vista through a vast series of ages, each marked by its own distinctive types of organic life, which, in proportion to their antiquity, departed more and more from the aspect of the living world.

Thus a hundred years ago, by the brilliant theory of Hutton and the fruitful generalization of Smith, the study of the earth received in our country the impetus which has given birth to the modern science of geology.

To review the marvellous progress which this science has made during the first century of its existence would require not one but many hours for adequate treatment. The march of discovery has advanced along a multitude of different paths, and the domains of Nature which have been included within the growing territories of human knowledge have been many and ample. Nevertheless, there are certain departments of investigation to which we may profitably restrict our attention on the present occasion, and wherein we may see how the leading principles that were proclaimed in this city a hundred years ago have germinated and borne fruit all over the world.

From the earliest times the natural features of the earth's surface have arrested the attention of mankind. The rugged mountain, the cleft ravine, the scarped cliff, the solitary boulder, have stimulated curiosity and prompted many a speculation as to their origin. The shells embedded by millions in the solid rocks of hills far removed from the sea have still further pressed home these "obstinate questionings." But for many long centuries the advance of inquiry into such matters was arrested by the paramount influence of orthodox theology. It was not merely that the Church opposed itself to the simple and obvious interpretation of these natural phenomena. So implicit had faith become in the accepted views of the earth's age and of the history of creation, that even laymen of intelligence and learning set themselves unbidden and in perfect good faith to explain away the difficulties which Nature so persistently raised up, and to reconcile her teachings with those of the theologians. In the various theories thus originating, the amount of knowledge of natural law usually stood in inverse ratio to the share played in them by an uncontrolled imagination. The speculations, for example, of Burnet, Whiston, Whitehurst, and others in this country, cannot be read now without a smile. In no sense were they scientific researches; they can only be looked upon as exercitations of learned ignorance. Springing mainly out of a laudable desire to promote what was believed to be the cause of true religion, they helped to retard inquiry, and exercised in that respect a baneful influence on intellectual progress.

It is the special glory of the Edinburgh school of geology to have cast aside all this fanciful trifling. Hutton boldly proclaimed that it was no part of his philosophy to account for the beginning of things. His concern lay only with the evidence furnished by the earth itself as to its origin. With the intuition of true genius he early perceived that the only solid basis from which to explore what has taken place in byegone time is a knowledge of what is taking place to-day. He thus founded his system upon a careful study of the processes whereby geological changes are now brought about. He felt assured that Nature must be consistent and uniform in her working, and that only in proportion as her operations at the present time are watched and understood will the ancient history of the earth become intelligible. Thus, in his hands, the investigation of the Present became the key to the interpretation of the Past. The establishment of this great truth was the first step towards the inauguration of a true science of the earth. The doctrine of the uniformity of causation in Nature became the fruitful principle on which the structure of modern geology could be built up.

Fresh life was now breathed into the study of the earth. A new spirit seemed to animate the advance along every pathway of inquiry. Facts that had long been familiar came to possess a wider and deeper meaning when their connection with each other was recognized as parts of one great harmonious system of continuous change. In no department of Nature, for example, was this broader vision more remarkably displayed than in that wherein the circulation of water between land and sea plays the most conspicuous part. From the earliest times men had watched the coming of clouds, the fall of rain, the flow of rivers, and had recognized that on this nicely adjusted machinery the beauty and fertility of the land depend. But they now learnt that this beauty and fertility involve a continual decay of the terrestrial surface; that the soil is a measure of this decay, and would cease to afford us maintenance were it not continually removed and renewed; that through the ceaseless transport of soil by rivers to the sea the face of the land is slowly lowered in level and carved into mountain and valley, and that the materials thus borne outwards to the floor of the ocean are not lost, but accumulate there to form rocks, which in the end will be upraised into new lands. Decay and renovation, in well-balanced proportions, were thus shown to be the system on which the existence of the earth as a habitable globe had been established. It was impossible to conceive that the economy of the planet could be maintained on any other basis. Without the circulation of water the life of plants and animals would be impossible, and with that circulation the decay of the surface of the land and the renovation of its disintegrated materials are necessarily involved.

As it is now so must it have been in past time. Hutton and Playfair pointed to the stratified rocks of the earth's crust as demonstrations that the same processes which are at work to-day have been in operation from a remote antiquity. By thus placing their theory on a basis of actual observation, and providing in the study of existing operations a guide to the interpretation of those in past times, they rescued the investigation of the history of the earth from the speculations of theologians and cosmologists, and established a place for it among the recognized inductive sciences. To the guiding influence of their philosophical system the prodigious strides made by modern geology are in large measure to be attributed. And here in their own city, after the lapse of a hundred years, let us offer to their memory the grateful homage of all who have profited by their labours.

But while we recognize with admiration the far-reaching influence of the doctrine of uniformity of causation in the investigation of the history of the earth, we must upon reflection admit that the doctrine has been pushed to an extreme perhaps not contemplated by its original founders. To take the existing conditions of Nature as a platform of actual knowledge from which to start in an inquiry into former conditions was logical and prudent. Obviously, however, human experience, in the few centuries during which attention has been turned to such subjects, has been too brief to warrant any dogmatic assumption that the various natural processes must have been carried on in the past with the same energy and at the same rate as they are carried on now. Variations in energy might have been legitimately conceded as possible, though not to be allowed without reasonable proof in their favour. It was right to refuse to admit the operation of speculative causes of change when the phenomena were capable of natural and adequate explanation by reference to causes that can be watched and investigated. But it was an error to take for granted that no other kind of process or influence, nor any variation in the rate of activity save those of which man has had actual cognizance, has played a part in the terrestrial economy. The uniformitarian writers laid themselves open to the charge of maintaining a kind of perpetual motion in the machinery of Nature. They could find in the records of the earth's history no evidence of a beginning, no prospect of an end. They saw that many successive renovations and destructions had been effected on the earth's surface, and that this long line of vicissitudes formed a series of which the earliest were lost in antiquity, while the latest were still in progress towards an apparently illimitable future.

The discoveries of William Smith, had they been adequately understood, would have been seen to offer a corrective to this rigidly uniformitarian conception, for they revealed that the crust of the earth contains the long record of an unmistakable order of progression in organic types. They proved that plants and animals have varied widely in successive periods of the earth's history, the present condition of organic life being only the latest phase of a long preceding series, each stage of which recedes further from the existing aspect of things as we trace it backward into the past. And though no relic had yet been found, or indeed was ever likely to be found, of the first living things that appeared upon the earth's surface, the manifest simplification of types in the older formations pointed irresistibly to some beginning from which the long procession had taken its start. If then it could thus be demonstrated that there had been upon the globe an orderly march of living forms from the lowliest grades in early times to man himself to day, and thus that in one department of her domain, extending through the greater portion of the records of the earth's history, Nature had not been uniform but had followed a vast and noble plan of evolution, surely it might have been expected that those who discovered and made known this plan would seek to ascertain whether some analogous physical progression from a definite beginning might not be discernible in the framework of the globe itself.

But the early masters of the science laboured under two great disadvantages. In the first place, they found the oldest records of the earth's history so broken up and effaced as to be no longer legible. And in the second place, they lived under the spell of that strong reaction against speculation which followed the bitter controversy between the Neptunists and Plutonists in the earlier decades of the century. They considered themselves bound to search for facts, not to build up theories; and as in the crust of the earth they could find no facts which threw any light upon the primeval constitution and subsequent development of our planet, they shut their ears to any theoretical interpretations that might be offered from other departments of science. It was enough for them to maintain, as Hutton had done, that in the visible structure of the earth itself no trace can be found of the beginning of things, and that the oldest terrestrial records reveal no physical conditions essentially different from those in which we still live. They doubtless listened with interest to the speculations of Kant, Laplace, and Herschel, on the probable evolution of nebulæ, suns, and planets, but it was with the languid interest attaching to ideas that lay outside of their own domain of research. They recognized no practical connection between such speculations and the data furnished by the earth itself as to its own history and progress.

This curious lethargy with respect to theory on the part of men who were popularly regarded as among the most speculative followers of science would probably not have been speedily dispelled by any discovery made within their own field of observation. Even now, after many years of the most diligent research, the first chapters of our planet's history remain undiscovered or undecipherable. On the great terrestrial palimpsest the earliest inscriptions seem to have been hopelessly effaced by those of later ages. But the question of the primeval condition and subsequent history of the planet might be considered from the side of astronomy and physics. And it was by investigations of this nature that the geological torpor was eventually dissipated. To our illustrious former President, Lord Kelvin, who occupied this chair when the Association last met in Edinburgh, is mainly due the rousing of attention to this subject. By the most convincing arguments he showed how impossible it was to believe in the extreme doctrine of uniformitarianism. And though, owing to uncertainty in regard to some of the data, wide limits of time were postulated by him, he insisted that within these limits the whole evolution of the earth and its inhabitants must have been comprised. While, therefore, the geological doctrine that the present order of Nature must be our guide to the interpretation of the past remained as true and fruitful as ever, it had now to be widened by the reception of evidence furnished by a study of the earth as a planetary body. The secular loss of heat, which demonstrably takes place both from the earth and the sun, made it quite certain that the present could not have been the original condition of the system. This diminution of temperature with all its consequences is not a mere matter of speculation, but a physical fact of the present time as much as any of the familiar physical agencies that affect the surface of the globe. It points with unmistakable directness to that beginning of things of which Hutton and his followers could find no sign.

Another modification or enlargement of the uniformitarian doctrine was brought about by continued investigation of the terrestrial crust and consequent increase of knowledge respecting the history of the earth. Though Hutton and Playfair believed in periodical catastrophes, and indeed required these to recur in order to renew and preserve the habitable condition of our planet, their successors gradually came to view with repugnance any appeal to abnormal, and especially to violent manifestations of terrestrial vigour, and even persuaded themselves that such slow and comparatively feeble action as had been witnessed by man could alone be recognized in the evidence from which geological history must be compiled. Well do I remember in my own boyhood what a cardinal article of faith this prepossession had become. We were taught by our great and honoured master, Lyell, to believe implicitly in gentle and uniform operations, extended over indefinite periods of time, though possibly some, with the zeal of partisans, carried this belief to an extreme which Lyell himself did not approve. The most stupendous marks of terrestrial disturbance, such as the structure of great mountain chains, were deemed to be more satisfactorily accounted for by slow movements prolonged through indefinite ages than by any sudden convulsion.

What the more extreme members of the uniformitarian school failed to perceive was the absence of all evidence that terrestrial catastrophes even on a colossal scale might not be a part of the present economy of this globe. Such occurrences might never seriously affect the whole earth at one time, and might return at such wide intervals that no example of them has yet been chronicled by man. But that they have occurred again and again, and even within comparatively recent geological times, hardly admits of serious doubt. How far at different epochs and in various degrees they may have included the operation of cosmical influences lying wholly outside the planet, and how far they have resulted from movements within the body of the planet itself, must remain for further inquiry. Yet the admission that they have played a part in geological history may be freely made without impairing the real value of the Huttonian doctrine, that in the interpretation of this history our main must be a knowledge of the existing processes of terrestrial change.

As the most recent and best known of these great transformations, the Ice Age stands out conspicuously before us. If any one sixty years ago had ventured to affirm that at no very distant date the snows and glaciers of the Arctic regions stretched southwards into France, he would have been treated as a mere visionary theorist. Many of the facts to which he would have appealed in support of his statement were already well known, but they had received various other interpretations. By some observers, notably by Hutton's friend, Sir James Hall, they were believed to be due to violent debacles of water that swept over the face of the land. By others they were attributed to the strong tides and currents of the sea when the land stood at a lower level. The uniformitarian school of Lyell had no difficulty in elevating or depressing land to any required extent. Indeed, when we consider how averse these philosophers were to admit any kind or degree of natural operation other than those of which there was some human experience, we may well wonder at the boldness with which, on sometimes the slenderest evidence, they made land and sea change places, on the one hand submerging mountain-ranges, and on the other placing great barriers of land where a deep ocean rolls. They took such liberties with geography because only well-established processes of change were invoked in the operations. Knowing that during the passage of an earthquake a territory bordering the sea may be upraised or sunk a few feet, they drew the sweeping inference that any amount of upheaval or depression of any part of the earth's surface might be claimed in explanation of geological problems. The progress of inquiry, while it has somewhat curtailed this geographical license, has now made known in great detail the strange story of the Ice Age.

There cannot be any doubt that after man had become a denizen of the earth, a great physical change came over the northern hemisphere. The climate, which had previously been so mild that evergreen trees flourished within ten or twelve degrees of the north pole, now became so severe that vast sheets of snow and ice covered the north of Europe and crept southward beyond the south coast of Ireland, almost as far as the southern shores of England, and across the Baltic into France and Germany. This Arctic transformation was not an episode that lasted merely a few seasons, and left the land to resume thereafter its ancient aspect. With various successive fluctuations it must have endured for many thousands of years. When it began to disappear it probably faded away as slowly and imperceptibly as it had advanced, and when it finally vanished it left Europe and North America profoundly changed in the character alike of their scenery and of their inhabitants. The rugged rocky contours of earlier times were ground smooth and polished by the march of the ice across them, while the lower grounds were buried under wide and thick sheets of clay, gravel, and sand, left behind by the melting ice. The varied and abundant flora which had spread so far within the Arctic circle was driven away into more southern and less ungenial climes. But most memorable of all was the extirpation of the prominent large animals which, before the advent of the ice, had roamed over Europe. The lions, hyænas, wild horses, hippopotami, and other creatures either became entirely extinct or were driven into the Mediterranean basin and into Africa. In their place came northern forms—the reindeer, glutton, musk ox, woolly rhinoceros, and mammoth.

Such a marvellous transformation in climate, in scenery, in vegetation and in inhabitants, within what was after all but a brief portion of geological time, though it may have involved no sudden or violent convulsion, is surely entitled to rank as a catastrophe in the history of the globe. It was probably brought about mainly if not entirely by the operation of forces external to the earth. No similar calamity having befallen the continents within the time during which man has been recording his experience, the Ice Age might be cited as a contradiction to the doctrine of uniformity, and yet it manifestly arrived as part of the established order of Nature. Whether or not we grant that other ice ages preceded the last great one, we must admit that the conditions under which it arose, so far as we know them, might conceivably have occurred before and may occur again. The various agencies called into play by the extensive refrigeration of the northern hemisphere were not different from those with which we are familiar. Snow fell and glaciers crept as they do to-day. Ice scored and polished rocks exactly as it still does among the Alps and in Norway. There was nothing abnormal in the phenomena save the scale on which they were manifested. And thus, taking a broad view of the whole subject, we recognize the catastrophe, while at the same time we see in its progress the operation of those same natural processes which we know to be integral parts of the machinery whereby the surface of the earth is continually transformed.

Among the debts which science owes to the Huttonian school, not the least memorable is the promulgation of the first well-founded conceptions of the high antiquity of the globe. Some six thousand years had previously been believed to comprise the whole life of the planet, and indeed of the entire universe. When the curtain was then first raised that had veiled the history of the earth, and men, looking beyond the brief span within which they had supposed that history to have been transacted, behold the records of a long vista of ages stretching far away into a dim illimitable past, the prospect vividly impressed their imagination. Astronomy had made known the immeasurable fields of space; the new science of geology seemed now to reveal boundless distances of time. The more the terrestrial chronicles were studied the farther could the eye range into an antiquity so vast as to defy all attempts to measure or define it. The progress of research continually furnished additional evidence of the enormous duration of the ages that preceded the coming of man, while, as knowledge increased, periods that were thought to have followed each other consecutively were found to have been separated by prolonged intervals of time. Thus the idea arose and gained universal acceptance that, just as no boundary could be set to the astronomer in his free range through space, so the whole of bygone eternity lay open to the requirements of the geologist. Playfair, re-echoing and expanding Hutton's language, had declared that neither among the records of the earth nor in the planetary motions can any trace be discovered of the beginning or of the end of the present order of things; that no symptom of infancy or of old age has been allowed to appear on the face of Nature, nor any sign by which either the past or the future duration of the universe can be estimated; and that although the Creator may put an end, as He no doubt gave a beginning, to the present system, such a catastrophe will not be brought about by any of the laws now existing, and is not indicated by anything which we perceive. This doctrine was naturally espoused with warmth by the extreme uniformitarian school, which required an unlimited duration of time for the accomplishment of such slow and quiet cycles of change as they conceived to be alone recognizable in the record of the earth's past history.

It was Lord Kelvin who, in the writings to which I have already referred, first called attention to the fundamentally erroneous nature of these conceptions. He pointed out that from the high internal temperature of our globe, increasing inwards as it does, and from the rate of loss of its heat, a limit may be fixed to the planet's antiquity. He showed that so far from there being no sign of a beginning, and no prospect of an end to the present economy, every lineament of the solar system bears witness to a gradual dissipation of energy from some definite starting-point. No very precise data were then, or indeed are now, available for computing the interval which has elapsed since that remote commencement, but he estimated that the surface of the globe could not have consolidated less than twenty millions of years ago, for the rate of increase of temperature inwards would in that case have been higher than it actually is; nor more than 400 millions of years ago, for then there would have been no sensible increase at all. He was inclined, when first dealing with the subject, to believe that from a review of all the evidence then available, some such period as 100 millions of years would embrace the whole geological history of the globe.

It is not a pleasant experience to discover that a fortune which one has unconcernedly believed to be ample has somehow taken to itself wings and disappeared. When the geologist was suddenly awakened by the energetic warning of the physicist, who assured him that he had enormously overdrawn his account with past time, it was but natural under the circumstances that he should think the accountant to be mistaken, who thus returned to him dishonoured the large drafts he had made on eternity. He saw how wide were the limits of time deducible from physical considerations, how vague the data from which they had been calculated. And though he could not help admitting that a limit must be fixed beyond which his chronology could not be extended, he consoled himself with the reflection that after all a hundred millions of years was a tolerably ample period of time, and might possibly have been quite sufficient for the transaction of all the prolonged sequence of events recorded in the crust of the earth. He was therefore disposed to acquiesce in the limitation thus imposed upon geological history.

But physical inquiry continued to be pushed forward with regard to the early history and the antiquity of the earth. Further consideration of the influence of tidal friction in retarding the earth's rotation, and of the sun's rate of cooling, led to sweeping reductions of the time allowable for the evolution of the planet. The geologist found himself in the plight of Lear when his bodyguard of one hundred knights was cut down. "What need you five-and-twenty, ten or five?" demands the inexorable physicist, as he remorselessly strikes slice after slice from his allowance of geological time. Lord Kelvin is willing, I believe, to grant us some twenty millions of years, but Prof. Tait would have us content with less than ten millions.

In scientific as in other mundane questions there may often be two sides, and the truth may ultimately be found not to lie wholly with either. I frankly confess that the demands of the early geologists for an unlimited series of ages were extravagant, and, even for their own purposes, unnecessary, and that the physicist did good service in reducing them. It may also be freely admitted that the latest conclusions from physical considerations of the extent of geological time require that the interpretation given to the record of the rocks should be rigorously revised, with the view of ascertaining how far that interpretation may be capable of modification or amendment. But we must also remember that the geological record constitutes a voluminous body of evidence regarding the earth's history which cannot be ignored, and must be explained in accordance with ascertained natural laws. If the conclusions derived from the most careful study of this record cannot be reconciled with those drawn from physical considerations, it is surely not too much to ask that the latter should be also revised. It has been well said that the mathematical mill is an admirable piece of machinery, but that the value of what it yields depends upon the quality of what is put into it. That there must be some flaw in the physical argument I can, for my own part, hardly doubt, though I do not pretend to be able to say where it is to be found. Some assumption, it seems to me, has been made, or some consideration has been left out of sight, which will eventually be seen to vitiate the conclusions, and which when duly taken into account will allow time enough for any reasonable interpretation of the geological record.

In problems of this nature, where geological data capable of numerical statement are so needful, it is hardly possible to obtain trustworthy computations of time. We can only measure the rate of changes in progress now, and infer from these changes the length of time required for the completion of results achieved by the same processes in the past. There is fortunately one great cycle of movement which admits of careful investigation, and which has been made to furnish valuable materials for estimates of this kind. The universal degradation of the land, so notable a characteristic of the earth's surface, has been regarded as an extremely slow process. Though it goes on without ceasing, yet from century to century it seems to leave hardly any perceptible trace on the landscapes of a country. Mountains and plains, hills and valleys, appear to wear the same familiar aspect which is indicated in the oldest pages of history. This obvious slowness in one of the most important departments of geological activity, doubtless contributed in large measure to form and foster a vague belief in the vastness of the antiquity required for the evolution of the earth.

But, as geologists eventually came to perceive, the rate of degradation of the land is capable of actual measurement. The amount of material worn away from the surface of any drainage-basin and carried in the form of mud, sand, or gravel, by the main river into the sea, represents the extent to which that surface has been lowered by waste in any given period of time. But denudation and deposition must be equivalent to each other. As much material must be laid down in sedimentary accumulations as has been mechanically removed, so that in measuring the annual bulk of sediment borne into the sea by a river, we obtain a clue not only to the rate of denudation of the land, but also to the rate at which the deposition of new sedimentary formations takes place.

As might be expected, the activities involved in the lowering of the surface of the land are not everywhere equally energetic. They are naturally more vigorous where the rainfall is heavy, where the daily range of temperature is large, and where frosts are severe. Hence they are obviously much more effective in mountainous regions than on plains; and their results must constantly vary, not only in different basins of drainage, but even, and sometimes widely, within the same basin. Actual measurement of the proportion of sediment in river water shows that while in some cases the lowering of the surface of the land may be as much as $\frac{1}{730}$ of a foot in a year, in others it falls as low as $\frac{1}{6800}$. In other words, the rate of deposition of new sedimentary formations, over an area of sea-floor equivalent to that which has yielded the sediment, may vary from one foot in 730 years to one foot in 6,800 years.

If now we take these results and apply them as measures of the length of time required for the deposition of the various sedimentary masses that form the outer part of the earth's crust, we obtain some indication of the duration of geological history. On a reasonable computation these stratified masses, where most fully developed, attain a united thickness of not less than 100,000 feet. If they were all laid down at the most rapid recorded rate of denudation, they would require a period of seventy-three millions of years for their completion. If they were laid down at the slowest rate they would demand a period of not less than 680 millions.

But it may be argued that all kinds of terrestrial energy are growing feeble, that the most active denudation now in progress is much less vigorous than that of bygone ages, and hence that the stratified part of the earth's crust may have been put together in a much briefer space of time than modern events might lead us to suppose. Such arguments are easily adduced and look sufficiently specious, but no confirmation of them can be gathered from the rocks. On the contrary, no one can thoughtfully study the various systems of stratified formations without being impressed by the fulness of their evidence that, on the whole, the accumulation of sediment has been extremely slow. Again and again we encounter groups of strata composed of thin paper-like laminæ of the finest silt, which evidently settled down quietly and at intervals on the sea bottom. We find successive layers covered with ripple-marks and sun-cracks, and we recognize in them memorials of ancient shores where sand and mud tranquilly gathered as they do in sheltered estuaries at the present day. We can see no proof whatever, nor even any evidence which suggests, that on the whole the rate of waste and sedimentation was more rapid during Mesozoic and Palæozoic time than it is to-day. Had there been any marked difference in this rate from ancient to modern times, it would be incredible that no clear proof of it should have been recorded in the crust of the earth.

But in actual fact the testimony in favour of the slow accumulation and high antiquity of the geological record is much stronger than might be inferred from the mere thickness of the stratified formations. These sedimentary deposits have not been laid down in one unbroken sequence, but have had their continuity interrupted again and again by upheaval and depression. So fragmentary are they in some regions, that we can easily demonstrate the length of time represented there by still existing sedimentary strata to be vastly less than the time indicated by the gaps in the series.

There is yet a further and impressive body of evidence furnished by the successive races of plants and animals which have lived upon the earth and have left their remains sealed up within its rocky crust. No one now believes in the exploded doctrine that successive creations and universal destructions of organic life are chronicled in the stratified rocks. It is everywhere admitted that, from the remotest times up to the present day, there has been an onward march of development, type succeeding type in one long continuous progression. As to the rate of this evolution precise data are wanting. There is, however, the important negative argument furnished by the absence of evidence of recognizable specific variations of organic forms since man began to observe and record. We know that within human experience a few species have become extinct, but there is no conclusive proof that a single new species has come into existence, nor are appreciable variations readily apparent in forms that live in a wild state. The seeds and plants found with Egyptian mummies, and the flowers and fruits depicted on Egyptian tombs, are easily identified with the vegetation of modern Egypt. The embalmed bodies of animals found in that country show no sensible divergence from the structure or proportions of the same animals at the present day. The human races of Northern Africa and Western Asia were already as distinct when portrayed by the ancient Egyptian artists as they are now, and they do not seem to have undergone any perceptible change since then. Thus a lapse of four or five thousand years has not been accompanied by any recognizable variation in such forms of plant and animal life as can be tendered in evidence. Absence of sensible change in these instances is, of course, no proof that considerable alteration may not have been accomplished in other forms more exposed to vicissitudes of climate and other external influences. But it furnishes at least a presumption in favour of the extremely tardy progress of organic variation.

If, however, we extend our vision beyond the narrow range of human history, and look at the remains of the plants and animals preserved in those younger formations which, though recent when regarded as parts of the whole geological record, must be many thousands of years older than the very oldest of human monuments, we encounter the most impressive proofs of the persistence of specific forms. Shells which lived in our seas before the coming of the Ice Age present the very same peculiarities of form, structure, and ornament which their descendants still possess. The lapse of so enormous an interval of time has not sufficed seriously to modify them. So too with the plants and the higher animals which still survive. Some forms have become extinct, but few or none which remain display any transitional gradations into new species. We must admit that such transitions have occurred, that indeed they have been in progress ever since organized existence began upon our planet, and are doubtless taking place now. But we cannot detect them on the way, and we feel constrained to believe that their march must be excessively slow.

There is no reason to think that the rate of organic evolution has ever seriously varied; at least no proof has been adduced of such variation. Taken in connection with the testimony of the sedimentary rocks, the inferences deducible from fossils entirely bear out the opinion that the building up of the stratified crust of the earth has been extremely gradual. If the many thousands of years which have elapsed since the Ice Age have produced no appreciable modification of surviving plants and animals, how vast a period must have been required for that marvellous scheme of organic development which is chronicled in the rocks!

After careful reflection on the subject, I affirm that the geological record furnishes a mass of evidence which no arguments drawn from other departments of Nature can explain away, and which, it seems to me, cannot be satisfactorily interpreted save with an allowance of time much beyond the narrow limits which recent physical speculation would concede.

I have reserved for final consideration a branch of the history of the earth which, while it has become, within the lifetime of the present generation, one of the most interesting and fascinating departments of geological inquiry, owed its first impulse to the far-seeing intellects of Hutton and Playfair. With the penetration of genius these illustrious teachers perceived that if the broad masses of land and the great chains of mountains owe their origin to stupendous movements which from time to time have convulsed the earth, their details of contour must be mainly due to the eroding power of running water. They recognized that as the surface of the land is continually worn down, it is essentially by a process of sculpture that the physiognomy of every country has been developed, valleys being hollowed out and hills left standing, and that these inequalities in topographical detail are only varying and local accidents in the progress of the one great process of the degradation of the land.

From the broad and guiding outlines of theory thus sketched we have now advanced amid ever-widening multiplicity of detail into a fuller and nobler conception of the origin of scenery. The law of evolution is written as legibly on the landscapes of the earth as on any other page of the Book of Nature. Not only do we recognize that the existing topography of the continents, instead of being primeval in origin, has gradually been developed after many precedent mutations, but we are enabled to trace these earlier revolutions in the structure of every hill and glen. Each mountain-chain is thus found to be a memorial of many successive stages in geographical evolution. Within certain limits, land and sea have changed places again and again. Volcanoes have broken out and have become extinct in many countries long before the advent of man. Whole tribes of plants and animals have meanwhile come and gone, and in leaving their remains behind them as monuments at once of the slow development of organic types, and of the prolonged vicissitudes of the terrestrial surface, have furnished materials for a chronological arrangement of the earth's topographical features. Nor is it only from the organisms of former epochs that broad generalizations may be drawn regarding revolutions in geography. The living plants and animals of to-day have been discovered to be eloquent of ancient geographical features that have long since vanished. In their distribution they tell us that climates have changed, that islands have been disjoined from continents, that oceans once united have been divided from each other, or once separate have now been joined; that some tracts of land have disappeared, while others for prolonged periods of time have remained in isolation. The present and the past are thus linked together not merely by dead matter, but by the world of living things, into one vast system of continuous progression.

In this marvellous increase of knowledge regarding the transformations of the earth's surface, one of the most impressive features, to my mind, is the power now given to us of perceiving the many striking contrasts between the present and former aspects of topography and scenery. We seem to be endowed with a new sense. What is seen by the bodily eye—mountain, valley, or plain—serves but as a veil, beyond which, as we raise it, visions of long-lost lands and seas rise before us in a far-retreating vista. Pictures of the most diverse and opposite character are beheld, as it were, through each other, their lineaments subtly interwoven and even their most vivid contrasts subdued idto one blended harmony. Like the poet, "we see, but not by sight alone;" and the "ray of fancy" which, as a sunbeam, lightened up his landscape, is for us broadened and brightened by that play of the imagination which science can so vividly excite and prolong.

Admirable illustrations of this modern interpretation of scenery are supplied by the district wherein we are now assembled. On every side of us rise the most convincing proofs of the reality and potency of that ceaseless sculpture by which the elements of landscape have been carved into their present shapes. Turn where we may, our eyes rest on hills that project above the lowland, not because they have been upheaved into these positions, but because their stubborn materials have enabled them better to withstand the degradation which has worn down the softer strata into the plains around them. Inch by inch the surface of the land has been lowered, and each hard rock successively laid bare has communicated its own characteristics of form and colour to the scenery.

If, standing on the Castle Rock, the central and oldest site in Edinburgh, we allow the bodily eye to wander over the fair landscape, and the mental vision to range through the long vista of earlier landscapes which science here reveals to us, what a strange series of pictures passes before our gaze! The busy streets of to-day seem to fade away into the mingled copsewood and forest of prehistoric time. Lakes that have long since vanished gleam through the woodlands, and a rude canoe pushing from the shore startles the red deer that had come to drink. While we look, the picture changes to a polar scene, with bushes of stunted Arctic willow and birch, among which herds of reindeer browse and the huge mammoth makes his home. Thick sheets of snow are draped all over the hills around, and far to the north-west the distant gleam of glaciers and snow-fields marks the line of the Highland mountains. As we muse on this strange contrast to the living world of to-day the scene appears to grow more Arctic in aspect, until every hill is buried under one vast sheet of ice, 2,000 feet or more in thickness, which fills up the whole midland valley of Scotland and creeps slowly eastward into the basin of the North Sea. Here the curtain drops upon our moving pageant, for in the geological record of this part of the country an enormous gap occurs before the coming of the Ice Age.

When once more the spectacle resumes its movement the scene is found to have utterly changed. The familiar hills and valleys of the Lothians have disappeared. Dense jungles of a strange vegetation—tall reeds, club-mosses, and tree-ferns—spread over the steaming swamps that stretch for leagues in all directions. Broad lagoons and open seas are dotted with little volcanic cones which throw out their streams of lava and showers of ashes. Beyond these, in dimmer outline and older in date, we descry a wide lake or inland sea, covering the whole midland valley and marked with long lines of active volcanoes, some of them several thousand feet in height. And still further and fainter over the same region, we may catch a glimpse of that still earlier expanse of sea which in Silurian times overspread most of Britain. But beyond this scene our vision fails. We have reached the limit across which no geological evidence exists to lead the imagination into the primeval darkness beyond.

Such in briefest outline is the succession of mental pictures which modern science enables us to frame out of the landscapes around Edinburgh. They may be taken as illustrations of what may be drawn, and sometimes with even greater fulness and vividness, from any district in these islands. But I cite them especially because of their local interest in connection with the present meeting of the Association, and because the rocks that yield them gave inspiration to those great masters whose claims on our recollection, not least for their explanation of the origin of scenery, I have tried to recount this evening. But I am further impelled to dwell on these scenes from an overmastering personal feeling to which I trust I may be permitted to give expression. It was these green hills and grey crags that gave me in boyhood the impulse that has furnished the work and joy of my life. To them, amid changes of scene and surroundings, my heart ever fondly turns, and here I desire gratefully to acknowledge that it is to their influence that I am indebted for any claim I may possess to stand in the proud position in which your choice has placed me.

SECTION A.

MATHEMATICS AND PHYSICS.

OPENING ADDRESS BY PROF. ARTHUR SCHUSTER, PH.D., F.R.S., F.R.A.S., PRESIDENT OF THE SECTION.

IN opening the proceedings of our Annual Meeting the temptation is great to look back on the year which has passed and to select for special consideration such work published during its course as may seem to be of the greatest importance. I fear, however, that a year is too short a time to allow us to form a fair estimate of the value of a scientific investigation. The mushroom, which shoots up quickly, only to disappear again, impresses us more than the slow-growing seedling which will live to be a tree, and it is difficult to recognize the scientific fungus in its early stage. But, although I do not feel competent to give you a review of the progress made in our subject during the last twelve months, there is one event to which some allusion should be made. It has been the sad duty of many of my predecessors to announce the death of successful workers in the field of science, but I believe I am unique in having the pleasure of recording the birth of a scientific man. At the beginning of this year there came into the world a being so brilliant that he could, without preparation, take up the work of the most eminent man amongst us. Believers in the transmigration of souls have speculated on the fact that Galileo's death and Newton's birth fell within a year of each other; but no event has ever happened so striking as that which took place on the 1st of January, when the mantle of Sir William Thomson fell on the infant Lord Kelvin. Those who have attended these meetings will feel with me that the honour done to our foremost representative, an honour which has been a source of pride and satisfaction to every student of science, could not altogether remain unnoticed in the section which owes him so much.

We are chiefly concerned here with the increase of scientific knowledge, and we derive pleasure in contrasting the minor state of ignorance of our own time with that which prevailed a hundred years ago. But when we contrast at the same time the refined opportunities of a modern research laboratory with the crude conditions under which the experimentalist had to work at the beginning of the century, we may fairly ask ourselves whether it is possible by means of any systematic course of study or by means of any organisation to accelerate our progress into the dark continent of science. A number of serious considerations arise in connection with this subject, and though I am not going to weary you by attempting an exhaustive discussion, I should like to draw your attention to a few matters which seem to me to be well worthy of the consideration of this Association. Changes are constantly made and proposed in our existing institutions, or new ones are suggested which are to serve the purpose of a more rapid accumulation of knowledge. I need only allude to the alterations in the curriculum of the science schools in our old Universities, made partly for the purpose of fitting their graduates for the conduct of original research, or to the national laboratory proposed by my predecessor in this chair for carrying out a certain kind of scientific investigation, which at present is left undone, or is done by private enterprise. Even our own Association has not escaped the evil eye of the reformer, and, like other institutions, it may be capable of improvement. But in choosing the direction in which a change may best be made, I think we may learn something from the way in which Nature improves its organisms. We are taught by biologists that natural selection acts by developing those qualities which enable each species best to survive the struggle for existence; useless organs die off or become rudimentary. Nature teaches us, therefore, how a beautiful complex of beings, mutually dependent on each other, is formed by improving those parts which are best and most useful, and letting the rest take care of itself. But in many of the changes which have been made or are proposed the process of reform is very different. The weakest points are selected, our attention is drawn to some failure or something in which we are excelled by other nations, and attempts are made to cure what perhaps had better be left to become rudimentary. The proceeding is not objectionable as long as the nourishment which is applied to develop the weaker organs is not taken from those parts which we should specially take care to preserve. To apply these reflections to the questions with which we are specially concerned, I should like to see it more generally recognized that although there is no struggle for existence between different nations, yet each nation, owing to a number of circumstances, possesses its own peculiarities, which render it better fitted than its neighbours to do some particular part of the work on which the progress of science depends. No country, for instance, has rivalled France in the domain of accurate measurement, with which the names of Regnault and Amagat are associated, and the International Bureau of Weights and Measures has its fitting home in Paris.[1] The best work of the German Universities seems to me to consist in the following up of some theory to its logical conclusions and submitting it to the test of experiment. I doubt whether the efforts to transplant the research work of German Universities into this country will prove successful. Does it not seem well to let each country take that share of work for which the natural growth of its character and its educational establishment best adapt it? Is it wise to remedy some weak point, to fill up undoubted gaps, if the soil that fills the gaps has to be taken from the hills and elevations which rise above the surrounding level?

As far as the work of this section is concerned the strongest domain of this country has been that of mathematical physics. But it is not to this that I wish specially to refer. Look at the work done in Great Britain during the last two centuries; the work not only in physics, but in astronomy, chemistry, biology. Is it not true that the one distinctive feature which separates this from all other countries in the world is the prominent part played by the scientific amateur, and is it not also true that our modern system of education tends to destroy the amateur?

By amateur I do not necessarily mean a man who has other occupations and only takes up science in his leisure hours, but rather one who has had no academical training, at any rate in that branch of knowledge which he finally selects for study. He has probably been brought up for some profession unconnected with science, and only begins his study when his mind is sufficiently developed to form an entirely unbiassed opinion. We may, perhaps, best define an amateur as one who learns his science as he wants it and when he wants it. I should call Faraday an amateur. He would have been impossible in another country; perhaps he would be impossible in the days of the Science and Art Department. Other names will occur to you, the most typical and eminent being that of Joule. It is not my purpose to discuss why distinguished amateurs have been so numerous in this country, but I am anxious to point out that we are in danger of losing one great and necessary factor in the origination of scientific ideas.

One of the distinctive features of an amateur is this, that he carries the weight of theories, often not the weight of knowledge, and, if I am right, there is a distinct advantage in having one section of scientific men beginning their work untrammelled by preconceived notions, which a systematic training in science is bound to instil. Whatever is taught in early age must necessarily be taught in a more or less dogmatic manner, and, in whatever way it is taught, experience shows that it is nearly always received in a dogmatic spirit. It seems important, therefore, to confine the early training to those subjects in which preconceived notions are considered an advantage. It is to me an uncongenial task to sound a note of warning to our old Universities, for the chief difficulties in which they are placed at present are due to the fact that they have given way too much to outside advice; but I cannot help expressing a strong conviction that their highly specialised entrance examinations are a curse to all sound school education, and will prove a still more fatal curse to what concerns us most nearly, the progress of scientific knowledge. If school examinations could be more general, if scientific theories could only be taught at an age when a man is able to form an independent judgment, there might be some hope of retaining that originality of ideas which has been a distinctive feature of this country, and enabled our amateurs to hold a prominent position in the history of science. At present a knowledge of scientific theories seems to me to kill all knowledge of scientific facts.

It is by no means true that a complete knowledge of everything that has a bearing on a particular subject is always necessary to success in an original investigation. In many cases such knowledge is essential, in others it is a hindrance. Different types of men incline to different types of research, and it is well to preserve the dual struggle. The engine which works out the great problems of nature may be likened to a thermodynamic machine. The amateur supplies the steam and the Universities supply the cold water; the former, boiling over often with ill-considered and fanciful ideas, does not like the icy douche, and the professional scientist does not like the latent heat of the condensing steam, but nevertheless the hotter the steam and the colder the water the better works the machine. Sometimes it happens that the boiler and cooler are both contained in the same brain, and each country can boast of a few such in a century, but most of us have to remain satisfied with forming only an incomplete part of the engine of research.

But while it is necessary to recognize the great work done by the unprofessional scientists, it seems not untimely to draw their attention to the damage done to themselves if they overstep their legitimate boundaries, and especially if they seek popular support for their theories, which have not received the approval of those who are competent to judge. An appeal from Alexander sober to Alexander drunk will not prove successful in the end.

The gradual disappearance of the amateur may be a necessary consequence of our increased educational facilities, and we must inquire whether any marked advantages are offered to us in exchange. There is one direction in which it would seem at first sight, at any rate, that a proper course of study could do much to facilitate the progress of research.

On another occasion I pointed out that two parties are necessary for every advance in science, the one that makes it and the one that believes in it. If the discoverer is born, and cannot be made, would it not be possible at any rate to train the judgment of our students so that they may form a sound opinion on the new theories and ideas which are presented to them? It is too early as yet to judge in how far our generation is better in this respect than the one that has gone before them, but on closer examination it does not seem to me to be obvious that any marked improvement is possible. Every new idea revolutionizing our opinions on some important question must necessarily take time before it takes a proper hold on the scientific world. Is it not true that anyone who can at once see the full importance of a new theory, and accept it in place of the one in which he has been brought up, must stand at a height almost equal to that of the originator? The more startling and fresh the new conception the fewer must be those who are ready to adopt it. But looking back at the history of science during the present century, is there much evidence that great discoveries have been seriously delayed by want of proper appreciation? We may hear of cases where important papers have been rejected by scientific societies, and occasionally a man of novel ideas may have been too much neglected by his contemporaries. I doubt whether such cases of apparent injustice can ever be avoided, and, simply looking back on the great changes involved in matters of primary importance, such as the undulatory theory of light, the conservation of energy, and the second law of thermodynamics, I cannot admit that there is much reason to be dissatisfied with the rate at which new theories have been received. Those who experience a temporary check, owing to the fact that public opinion is not ripe for their ideas, are often amply rewarded after the lapse of a few years. The disappointment which Joule may have felt during the time his views met with adverse criticisms from the official world of science was no doubt amply compensated by the pleasure with which he watched the subsequent progress of research in the new domain which his discoveries have opened out.

---

[1] Much of the good work done by this Bureau remains unknown, owing to the miserly way in which their publications are circulated. No copies are supplied even to the University libraries. The explanation, of course, is "want of funds." In other words, England, France, and Germany, together with other nations, unite to do a certain kind of work, but cannot afford to distribute a few copies of the publication to the public for whose benefit the work is undertaken.

The point is not one of academic interest only, for the fear of repressing some important new discovery has a detrimental influence in another direction. The judgment of the scientific world seems to me to be tending too much towards leniency to apparently absurd theories, because there is a remote chance that they may contain some germ of real value. A new truth will not be found to suffer ultimately by adverse and even unreasonable criticism, while bad theories and bad reasoning, supported by the benevolent neutrality of those to whose judgment the scientific world looks for guidance, are harmful in many ways. They block the way to an independent advance and encourage hasty and ill-considered generalizations. The conclusions I should draw from the considerations I have placed before you are these: I believe that a reasonable censorship exercised by our scientific societies is good and necessary; that those whose fate it is to be called on to express an opinion on some work or theory should do so fearlessly according to their best judgment. Their opinion may be warped by prejudice, but I think it is better that they should incur the risk of being ultimately found to be wrong than that they should help in the propagation of bad reasoning. There is one matter, however, on which all opinions must agree. Worse than bad theory or logic is bad experimental work. Should we then not rigorously preserve any influence or incentive which encourages the beginner to avoid carelessness and to consider neither time nor trouble to secure accuracy? There is no doubt to my mind that the prospect of admission to the Royal Society has been most beneficial in this respect, and that the honourable ambition to see his paper published in the "Transactions" of that Society has preserved many a student from the premature publication of unfinished work.

One of the principal obstacles to the rapid diffusion of a new idea lies in the difficulty of finding suitable expression to convey its essential point to other minds. Words may have to be strained into a new sense, and scientific controversies constantly resolve themselves into differences about the meaning of words. On the other hand, a happy nomenclature has sometimes been more powerful than rigorous logic in allowing a new train of thought to be quickly and generally accepted.

A good example is furnished by the history of the science of energy. The principle of the conservation of energy has undoubtedly gained a more rapid and general acceptance than it would otherwise have had by the introduction of the word potential energy. A great theorem, which in itself seems to me to be an intricate one, has been simplified by calling something energy which, in the first place, is only a deficiency of kinetic energy. The only record I can find on the history of the expression is given in Tait's "Thermodynamics," wherein the term statical energy is ascribed to Lord Kelvin, and that of potential energy to Rankine. It would be of interest to have a more detailed account on the origin of an expression which has undoubtedly had a marked influence not only on the physics, but also on the metaphysics of our time. But while fully recognizing the very great advantage we have derived from this term "Potential Energy," we ought not, at the same time, to lose sight of the fact that it implies something more than can be said to be proved. It is easy to overstep the legitimate use of the word. Thus, when Professor Lodge[1] attempts to prove that action at a distance is not consistent with the doctrine of energy, he cannot, in my opinion, justify his position except by assuming that all energy is ultimately kinetic. That is a plausible but by no means a necessary theory. Efforts have been made to look on energy as on something which can be labelled and identified through its various transformations. Thus we may feel a certain bit of energy radiating from a coal-fire, and if our knowledge was complete, we ought to be able to fix the time at which that identical bit of energy left the sun and arrived on the surface of the earth, setting up a chemical action in the leaves of the plant from which the coal has been derived. If we push this view to a logical conclusion, it seems to me that we must finally arrive at an atomic conception of energy which some may consider an absurdity.

Let, for instance, a number of particles P_1, P_2, &c., in succession, strike another particle Q. How can we in the translatory energy of the latter identify the parts which P_1, P_2, &c., have contributed? According to Professor's Lodge's view, we should be able to do so, for if the particle Q in its turn gives up its energy to others, say R_1, R_2, R_3, &c., we ought to be able to say whether the energy of P_1 has ultimately gone into R_1 or into R_2, or is divided between them. It is only by imagining that all energy is made up of a finite number of bits, which pass from one body to another, that we can defend the idea of considering energy as capable of being "labelled."

In the expressions we adopt to prescribe physical phenomena we necessarily hover between two extremes. We either have to choose a word which implies more than we can prove, or we have to use vague and general terms which hide the essential point, instead of bringing it out. The history of electrical theories furnishes a good example. The terms positive and negative electricity committed us to something definite; we could reckon about quantities of electricity, and form some definite notion of electrical currents as a motion of the two kinds of electricity in opposite directions. Now we have changed all that; we speak of electric displacements, but safeguard ourselves by saying that a displacement only means a vector quantity, and not necessarily an actual displacement. We speak of lines and tubes of force not only as a help to realize more clearly certain analytical results, but as implying a physical theory to which, at the same time, we do not wish to commit ourselves. I do not find any fault with this, for it is a perfectly legitimate and necessary process to state the known connection between physical phenomena in some form which introduces the smallest number of assumptions. But the great question "What is electricity?" is not touched by these general considerations. The brilliant success with which Maxwell's investigations have been crowned is apt to make us overrate the progress made in the solution of that question. Maxwell and his followers have proved the important fact that optical and electrical actions are transmitted through the same medium. We may be said to have arrived in the subject of electricity at the stage in which optics was placed before Young and Fresnel hit on the idea of transverse vibrations, but there is no theory of electricity in the sense in which there is an elastic solid theory of light.

If the term electrical displacement was taken in its literal sense, it would mean that the electric current consists of the motion of the ether through the conductor. This is a plausible hypothesis, and one respecting which we may obtain experimental evidence. The experiments of Rayleigh and others have shown that the velocity of light in an electrolyte, through which an electric current is passing, is, within experimental limits, the same with and against the current. This result shows that if an electrical current means a motion of the ether the velocity of the medium cannot exceed ten metres a second for a current density of one ampère per square centimetre. This, then, is the upper limit for a possible velocity of the medium; can we find a lower limit? The answer to that question depends on the interpretation of a well-known experiment of Fizeau's, who found that the speed of light is increased if it travels through water which moves in the same direction as the light. If this experiment implies that the water carries the ether with it, and if a motion of the ether means an electric current, we should be led to the conclusion that a current of water should deflect a magnet in its neighbourhood. An experiment made to that effect would almost certainly give a negative result, and would give us a lower limit for the velocity of the medium corresponding to a given current. Such an experiment, together with that of Rayleigh, would probably dispose of the theory that an electric current is due to a translatory velocity of the medium. This would be an important step, and it would be worth while to arrive at a final settlement of the question.[1] The whole question of the relation between the motion of matter and motion of the medium is a vital one, and we shall probably not make any serious advances until experiment has found a new opening. But we must expect many negative results before some clue is discovered. Nor can we attach much importance to negative results unless they are made by some one in whose care and judgment we place full reliance. We should all the more, therefore, recognize the courage and perseverance of those who spend their valuable time in such investigations as Prof. Lodge has recently undertaken. That ultimately some relation will be found between moving matter and electrical action there is no reasonable doubt.

---

[1] *Phil. Mag.* vol. xi. p. 36 (1881).

[1] Fizeau's results must either be due to the motion of matter through the medium or to the fact that moving matter carries the ether with it. If it is due to the former cause, and matter does *not* carry the ether with it, may we not consider that matter moving through the ether, that is a relative motion of matter and ether, must produce effects equal and opposite to those of ether moving through matter? In that case the reasoning in the text would, *mutatis mutandis*, hold good.

One of the most hopeful openings for new investigations has always been found in the pursuing of a theory to its logical conclusions, and there is one result of the electromagnetic theory of light which has not, in my opinion, received the share of attention which it deserves.

When sound passes through air it is propagated more quickly with the wind than against it, and we may easily find the velocity relative to the earth by combining the ordinary sound velocity with the velocity of the wind. Similarly, when any waves pass through a medium moving with uniform velocity, the waves being due to internal stresses in the medium, we may treat of the velocity of the waves independently of that of the medium, and say that the wave-velocity in the direction of motion of the medium, and relative to a fixed body, is the sum of the wave-velocity, calculated on the supposition that the medium is at rest and the velocity of the medium. Prof. J. J. Thomson,[1] applying Maxwell's equations, has arrived at a different result for electromagnetic waves, and has come to the conclusion that in order to get the velocity of light along a stream of flowing water we have to add to the velocity of light only half the velocity of water. The following considerations suggest themselves to me with respect to this result. Maxwell's theory is founded on certain observed effects, which all depend on the relative motion of matter. A result such as the one referred to implies actions depending on absolute motion, and appears therefore to point to something which has been introduced into the equations for which there is no experimental evidence. The only assumption clearly put down by Maxwell is that electromagnetic actions are transmitted through the medium, and it is possible that that assumption necessarily carries Prof. J. J. Thomson's result with it. If a careful examination of the subject should show that this is the case, we are brought face to face with a serious difficulty. It is said, with justice, to be one of the great advantages of Maxwell's theory that it does away with action at a distance; but what do we gain if we replace action at a distance by something infinitely more difficult to conceive, namely, internal stresses of a medium depending on the velocity of the medium through space? I can only see one loophole through which to escape, namely, that Maxwell's medium is not homogeneous, but consists of two parts, and that if we speak of the medium as moving, we mean the motion of one of these parts relative to the other.

While we may hope to obtain important results from an investigation of the relation between what we call electricity and the medium, we must not lose sight of another avenue, namely, the relation between electricity and chemical effects. The passage of electricity through gases presents us with a complicated problem to which a number of physicists have given their attention of late years. There seems no reasonable doubt that electricity in a gas is conveyed by the diffusion of particles conveying high charges, probably identical with those carried by the electrolytic ion. The fact that this convection is a process of diffusion with comparatively small velocity is shown by the experimental result that the path of the discharge is affected by any bodily motion of the gas which conveys the current. Even the convection currents due to the heat produced by the discharge itself are sufficient to deflect the luminous column which marks the passage of the current.

The most puzzling fact, however, connected with the discharge of electricity through gases consists in the absence of symmetry at the positive and negative poles. There must be some difference between a positively and negatively charged atom which seems of fundamental importance in the relation between matter and what we call electricity. A discussion of the various phenomena attending the discharge of electricity through gases seems to me to point to a conclusion which may possibly prove a step in the right direction.

A surface of separation between bodies having different conductivities becomes electrified by the passage of a current, while at the surface between two chemically distinct bodies we have, according to Helmholtz, a sheet covered at the two sides with opposite electricities. These surface electrifications are not merely imaginary layers invented to satisfy mathematical surface conditions. They can be proved to be realities. Thus, when one electrolyte floats on another, the specific resistances being different, we often observe secondary chemical effects due to the action of the ions which carry the surface electrification.

If the passage of electricity from the solid to the gas involves some work done, we must expect a double sheet of electricity at the boundary, the gas in contact with the kathode becoming positively, and that in contact with the anode negatively, electrified. *A priori* we can form no idea how a layer of gas, the atoms of which carry charges, will behave. The ordinary proof that all electrification must be confined to the surface implies that all forces act according to the law of the inverse square, but where we have also to consider molecular forces, I see no reason why the electrification at a surface may not stretch across a layer having a thickness comparable with the mean free path of the molecule. It is here that there seems to be the fundamental difference between positive and negative electricity. A negative electrification of the gas, like that of a solid or a liquid, seems always confined to the surface, and no one has ever observed a volume electrification of negative electricity. The case is different for the positively electrified part of the gas. Wherever from other considerations we should expect a positively electrified surface sheet, we always get a layer of finite thickness. The result implies a different law of impact between positively and negatively electrified ions, but I see no inherent improbability in this. That the kathode let into a gas is surrounded by a positively electrified layer of finite thickness extending outwards must be considered as an established fact, and several of the characteristic features of the discharge are explained by it. The large fall of potential at the kathode can also be explained on the view which I have put forward, for in order to keep up the discharge there must be a sufficient normal force at the surface, and if this force is not confined to the surface, but necessarily stretches across a finite layer, the fall of potential must be multiplied a great number of times. Similarly Goldstein has shown that some of the phenomena of the kathode are observed at every place at which the positive current flows from a wide to a narrow part of a column of gas. At such places we should expect a positive surface electrification, and here, again, the whole appearance tends to show that we are dealing with a positive volume electrification. No corresponding phenomena are observed when the current passes from the narrow to the wide part.

The fact that in all cases experimented upon positive volume electrifications are observed but never similar negative electrifications is surely of significance.

Some of the results recently brought to light by investigations on the discharge of electricity have interesting cosmical applications. Thus it is found that such a discharge through any part of a vessel containing a gas converts the whole gas into a conductor.[1] The dissociation which we imagine to take place in a liquid before electrolytic conduction takes place must be artificially produced in a gas by the discharge itself. We may imitate in gases which have thus been rendered conductive many of the phenomena hitherto restricted to liquids: thus I hope to bring to the notice of this meeting cases of primary and secondary cells in which the electrolyte is a gas. There are other ways in which a gas can be put into that sensitive state in which we may treat it as a conductor, and we have every reason to suppose that the upper regions of our atmosphere are in this state. The principal part of the daily variation of the magnetic needle is due to causes lying outside the surface of the earth, and is in all probability only an electro-magnetic effect due to that bodily motion in our atmosphere which shows itself in the diurnal changes of the barometer. A favourite idea of the late Prof. Balfour Stewart will thus probably be confirmed. The difference in the diurnal range between times of maximum and times of minimum sun-spots is accounted for by the fact that the atmosphere is a better conductor at times of maximum sun-spots.

The mention of sun-spots raises a point not altogether new to this section. Careful observation of celestial phenomena may suggest to us the solution of many mysteries which are now puzzling us. Consider, for instance, how long it would have taken to prove the universal property of gravitational attraction if the record of planetary motion had not come to the philosopher's help. And surely the most casual observation of cosmical effects teaches us how much we have yet to learn.

---

[1] *Phil. Mag.*, vol. ix. p. 284 (1880).

[1] An experiment by Hittorf (*Wied. Ann.* vii. p. 614) suggested the probability of this fact, which was proved independently by Arrhenius and myself.

The statement of a problem occasionally helps to clear it up, and I may be allowed, therefore, to put before you some questions, the solution of which seems not beyond the reach of our powers.

1. Is every large rotating mass a magnet? If it is, the sun must be a powerful magnet. The comets' tails, which eclipse observations show stretching out from our sun in all directions, probably consist of electric discharges. The effect of a magnet on the discharge is known, and careful investigations of the streamers of the solar corona ought to give an answer to the question which I have put.[1]

2. Is there sufficient matter in interplanetary space to make it a conductor of electricity? I believe the evidence to be in favour of that view. But the conductivity can only be small, for otherwise the earth would gradually set itself to revolve about its magnetic pole. Suppose the electric resistance of interplanetary space to be so great that no appreciable change in the earth's axis of rotation could have taken place within historical times, is it not possible that the currents induced in planetary space by the earth's revolution may, by their electromagnetic action, cause the secular variation of terrestrial magnetism? There seems to me to be here a definite question capable of a definite answer, and as far as I can judge without a strict mathematical investigation the answer is in the affirmative.

3. What is a sunspot? It is, I believe, generally assumed that it is analogous to one of our cyclones. The general appearance of a sunspot does not show any marked cyclonic motion, though what we see is really determined by the distribution of temperature and not by the lines of flow. But a number of cyclones clustering together like the sunspots in a group should move round each other in a definite way, and it seems to me that the close study of the relative positions of a group of spots should give decisive evidence for or against the cyclone theory.

4. If the spot is not due to cyclonic motion, is it not possible that electric discharges setting out from the sun, and accelerating artificially evaporation at the sun's surface, might cool those parts from which the discharge starts, and thus produce a sunspot? The effects of electric discharges on matters of solar physics have already been discussed by Dr. Huggins.

5. May not the periodicity of sunspots, and the connection between two such dissimilar phenomena as spots on the sun and magnetic disturbances on the earth, be due to a periodically recurring increase in the electric conductivity of the parts of space surrounding the sun? Such an increase of conductivity might be produced by meteoric matter circulating round the sun.

6. What causes the anomalous law of rotation of the solar photosphere? It has long been known that groups of spots at the solar equator perform their revolution in a shorter time than those in a higher latitude; but spots are disturbances which may have their own proper motions. Duner[2] has shown, however, from the displacement of the Fraunhofer lines, that the whole of the layer which produces these lines follows the same anomalous law, the angular velocity at a latitude of 75° being 30 per cent. less than near the equator.[3] As all causes acting within the sun might cause the angular velocity of the sun to be smaller at the equator than at other latitudes, but could not make it greater, the only explanation open to us is an outside effect either by an influx of meteoric matter, as suggested by Lord Kelvin, or in some other way. If we are to trust Dr. Welsing's result that faculæ which have their seat below the photosphere revolve in all latitudes with the same velocity, which is that of the spot velocity in the equatorial region, we should have to find a cause for a retardation in higher latitudes rather than for an acceleration at the equator. The exceptional behaviour of the solar surface seems to me to deserve very careful attention from solar physicists. Its explanation will probably carry with it that of many other phenomena.

In conclusion, I should like to return for an instant to the question whether it is possible by any means to render the progress of science more smooth and swift. If there is any truth in the idea that two types of mind are necessary, the one corresponding to the boiler and the other to the cooler of a steam-engine, it must also be true that some place must be found where the two may bring their influence to bear on each other. I venture to think that no better ground can be chosen than that supplied by our meetings. We hear it said that the British Association has fulfilled its object; we are told that it was originally founded to create a general interest in scientific problems in the towns in which it meets; and now that popular lectures and popular literature are supposed to perform that work more satisfactorily, we are politely asked to commit the happy despatch. There is no need to go back to the original intention of those who have founded this institution, which has at any rate adapted itself sufficiently well to the altered circumstances to maintain a beneficial influence in scientific research.

The free discussion which takes place in our sections, the interchange of ideas between men who during the rest of the year have occupied their minds, perhaps too much, with some special problem, the personal intercourse between those who are beginning their work with sanguine expectations, and those who have lost the first freshness of their enthusiasm, should surely one and all ensure a long prosperity to our meetings. If we cannot claim any longer to sow the seeds of scientific interest in the towns we visit, because the interest is established, we can at any rate assure those who so kindly offer us hospitality that they are helping powerfully in the promotion of the great object which we all have at heart.

SECTION B.

CHEMISTRY.

OPENING ADDRESS BY PROF. HERBERT McLEOD, F.R.S., F.C.S., PRESIDENT OF THE SECTION.

IN endeavouring to prepare myself to properly fulfil the duties of President of this Section, to which I have been elected, and for which honour I am much indebted to the council and members of the Association (although I am only too well aware that the position might have been more efficiently filled by many others), I naturally looked at the reports of the previous meetings held in Edinburgh in 1834, 1850, and 1871, and it appears that on the first two occasions an address was not given by the president, a custom the discontinuance of which I have, at the present moment, much reason to regret.

At the meeting in 1834 a committee was appointed consisting of Dr. Dalton, Dr. Hope, Dr. T. Thomson, Mr. Whewell, Dr. Turner, Prof. Miller, Dr. Gregory, Dr. Christison, Mr. R. Phillips, Mr. Graham, Prof. Johnston, Dr. Faraday, Prof. Daniell, Dr. Clark, Prof. Cumming, and Dr. Prout, to report at the next meeting their opinion on the adoption of an uniform set of chemical symbols. Dr. Turner to be secretary.

In the following year the report contains: "Report of the Committee on Chemical Notation. Dr. Turner, the chairman of the committee appointed to take into consideration the adoption of an uniform system of chemical notation, made a report to the following effect:—

"1. That the majority of the Committee concur in approving of the employment of that system of notation which is already in general use on the Continent, though there exists among them some difference of opinion on points of detail.

"2. That they think it desirable not to deviate in the manner of notation from algebraic usage except so far as convenience requires.

"3. That they are of opinion that it would save much confusion if every chemist would always state explicitly the exact *quantities* which he intends to represent by his symbols.

"Dr. Dalton stated to the Chemical Section his reasons for preferring the symbols which he had himself used from the commencement of the atomic theory in 1803, to the Berzelian system of notation subsequently introduced. In his opinion regard must be had to the arrangement and equilibrium of the atoms (especially elastic atoms) in every compound atom, as well as to their number and weights. A system either of *arrangements* without *weights*, or of *weights* without *arrangements*, he considered only half of what it should be."

---

[1] The efforts of Mr. Bigelow have a bearing on this point, also some remarks which I have made in a lecture before the Royal Institution (*Proc. Roy, Inst.* 1891), but nothing decisive can be asserted at present.

[2] Oefvers. af Kongl. Veterrk. Ak. Forhandl., 47, 1890.

[3] Although the importance of M. Duner's results would make an independent investigation desirable, the measurements of Mr. Crew, who by a much inferior method arrived at other results, cannot have much weight as compared with those of Duner.

We can all sympathize with the members of the section of 1834 in their desire to obtain an uniform system of chemical notation, for at that time several very different systems seem to have been in use. Although the report is a short one, it probably directed the attention of chemists to the desirability of avoiding confusion by the use of various systems, and since that period many advances have been made.

There is now little necessity for every chemist to "state explicitly the exact *quantities* which he intends to represent by his symbols" for the accurate determinations of atomic weights by many chemists—and we must not omit to mention the work of Stas (whose death we have had to deplore since the last meeting of the British Association)—have given us a series of numbers which are in the hands of all chemists, so that, except in the cases where great refinement is requisite (or when the atomic weight has not been universally accepted) there is no need to state the values of the symbols.

That great advances have been made in chemical notation is well known to all; even in my own short experience I have had to learn several different methods. When I began to work at chemistry I was told that sulphate of lead was to be expressed by the formula PbO,SO_3. Hofmann taught me that it should be $PbSO_4$; then Gerhardt doubled the atomic weights of oxygen and sulphur and the formula became Pb_2SO_4; Cannizzaro showed that the atomic weight of lead should also be doubled, and the formula again became $PbSO_4$, but representing twice as much as formerly; then Frankland taught me to write SO_2Pbo'' as the expression of the graphic formula—

which not only states that the compound contains 207 of lead, 32 of sulphur, and 64 of oxygen, but that the sulphur is hexad, and is combined with two atoms of dyad oxygen, and with a dyad compound radical containing one atom of lead and two of oxygen; and of all the formulæ just given this is the only one which satisfies the requirements which Dalton thought necessary in 1835, namely, to indicate not only the weights of the elements present, but also their arrangement. It may be objected that we do not know that this formula really represents the arrangements of the atoms in plumbic sulphate, but there can be very little doubt that the four atoms of oxygen in the compound are not all in the same condition, for if we examine the properties of sulphuric acid (from which the sulphate of lead is derived by the replacement of the hydrogen by lead), we find that two of the atoms of oxygen are more closely associated with the hydrogen than are the other two, and, as there is some evidence, although perhaps not very conclusive, that sulphur may be capable of combining with six monad atoms, although no such compound is yet known, it does not seem unreasonable to suppose that sulphuric acid is really:—

What the nature of the attraction that holds the atoms together may be is not known, but it is more probably of a character similar to that of gravity which holds together sun and planets, than of the nature of cohesion which would hold the atoms rigidly together; the atoms in each molecule are therefore most probably in a state of rotation around, or of vibration to and from, the central atom which holds them together. The pictorial representation in a plane does not therefore truly express the position of the atoms, but merely the relations existing between them. In organic chemistry the use of formulæ expressing such a relation has become indispensable, and in inorganic chemistry I believe such a system is very useful.

Recently this system has been found insufficient for the requirements of organic chemistry, and recourse has been had to the figure of a tetrahedron to represent the atom of carbon, other atoms being attached to the solid angles; in this way the position of the atoms in space is more or less expressed.

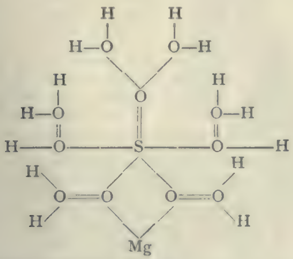
There are many cases, however, in which the atomicity theory fails us. At first it seemed probable that the atomicity of an element varied in pairs of attractions, that is, an element might be monad, triad, or pentad, but not dyad or tetrad; or it might be dyad, tetrad, or hexad, but not triad or pentad; but some great difficulties have been encountered. Thus nitrogen, which is pentad in ammonic chloride and triad in ammonia, forms the compound nitric oxide, NO, in which it would appear to be dyad; it has been suggested, however, that in this body the nitrogen is really triad, and that it possesses a "free bond." Now the idea of a "free bond" seems contrary to the principles of atomicity, since it is on the belief that such a free bond is impossible that the explanation of the existence of elementary molecules is formed, for it is said that when hydrogen is liberated two atoms unite to form a molecule, so that their mutual attractions may be satisfied. Nevertheless nitric oxide is a very active body, uniting readily with other substances, so the free bond seems to be on the look out for other kinds of matter, but to have no attraction for the free bond of another molecule of nitric oxide. As the molecule of nitric peroxide is variable by alterations of temperature, being N_2O_4 at low and NO_2 at high temperatures, it seemed not impossible that at the ordinary atmospheric temperature nitric oxide was a simplified or dissociated molecule, and that if the temperature were sufficiently reduced it would be found that its molecule would be N_2O_2, and thus it would contain triad nitrogen without a free bond. The density of the gas has, however, been determined at a temperature as low as $-73°$ and the molecule is still NO. Another important exception to the variation of the atomicity of an element in pairs was furnished by the investigations of Sir Henry Roscoe on the chlorides of vanadium; this element which, from analogy, should be a triad or a pentad, appears to form a chloride of the composition VCl_4. Again, the molecule of peroxide of chlorine is ClO_2, which would make chlorine a tetrad or the compound must have a free bond.

Another set of phenomena which the atomicity theory will not explain is the existence of well-defined crystalline salts containing what is called water of crystallization. This water is in many cases held with considerable pertinacity, the body appearing to be a veritable chemical compound. But water appears to be a saturated body, the attractions of the oxygen being satisfied by those of the hydrogen. It is true that water acts vigorously on other compounds, as on metallic oxides to form hydrates, and on some anhydrides to form acids, but these appear to be phenomena of double decomposition; thus the combination of water with sodic oxide and nitric anhydride respectively may be expressed by the equations

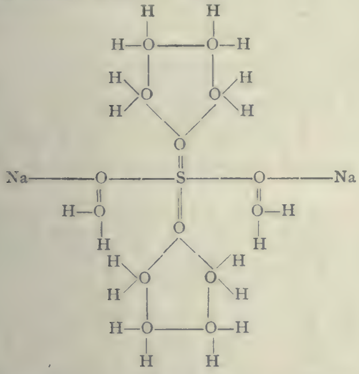
$$OH_2 + ONa_2 = OHNa + ONaH \text{ and}$$
$$OH_2 + O(NO_2)_2 = OH(NO_2) + O(NO_2)H.$$

In the combination of water with an anhydrous salt, a phenomenon often accompanied by great rise of temperature, there does not appear to be a double decomposition. That there is a chemical combination of some sort is shown by the changes of properties produced, crystalline form and colour being both sometimes altered. Compounds so produced have been called "molecular compounds" to imply that saturated molecules are in some way or another combined, the combination being different from "atomic combination," in which the atoms are directly united according to their valencies. Another explanation has been suggested by assuming that there is some "residual affinity" not saturated by the constituents of the body, and that this residual affinity enables bodies to unite in a less stable manner than in most compounds. But are not these terms—"molecular combination" and "residual affinity"—analogous to the term "catalysis," merely *words* to express—not to explain—what we do not understand? If "residual affinity" really exists, it must reside in the oxygen of the water, or in the hydrogen, or both; if so, what will happen to some of the complex constitutional formulæ of the organic chemist in which the carbon is tetrad, the oxygen dyad, and the hydrogen monad? If any of these elements have a residual affinity should we not expect to find additional unions between some of the atoms of the same molecule over and above those represented by the formula?

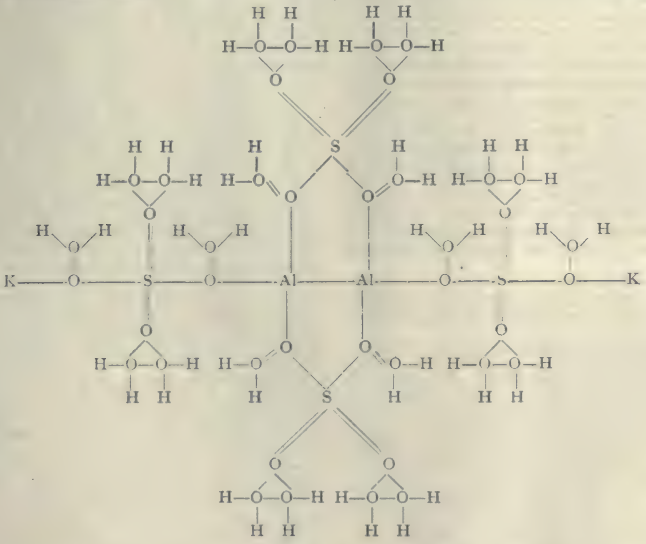
Oxygen may be tetrad, for which there is evidence in OAg_4. Under these circumstances water is by no means a saturated compound, and there would be no difficulty in explaining the combination of water with oxygen salts. Thus crystallized magnesic sulphate, $MgSO_5$, $7OH_2$ or SOHoMgo″, $6OH_2$ would be—



and sodic sulphate, Na_2SO_4, $10OH_2$:—



Even alum, with its 24 molecules of water of crystallization, may be expressed by an appalling formula :—



There is certainly a symmetry about the formula, and it will be found that 16 of the molecules of water are in a different position from the remaining 8 ; this probably has no significance, although Graham found that crystallized alum at a temperature of 61° lost 18 molecules of water ; if he had used a temperature a few degrees lower he might have found that only 16 passed off !

By a little stretching of the imagination and altering the atomicities of the elements to suit each particular case, no doubt graphic formulæ might be made for all crystalline salts, but they would be perfectly artificial, and not much good is likely to come from the attempt.

I fear we are driven to the conclusion, that, notwithstanding all the progress that has been made in chemical science during the last fifty-eight years, we have not yet reached a method of notation that would have satisfied Dr. Dalton in 1834.

But since that time we have learnt that our formulæ ought to show even more than the number and position of the atoms of a compound ; we should like them to indicate the amount of potential energy residing in a body, and our equations ought to indicate the amount of heat generated by a chemical change. Let us hope that before the next meeting of the British Association in Edinburgh these desirable developments will have been accomplished.

A short time ago I mentioned the word catalysis as being employed to express certain chemical actions which cannot be explained. It is applied to those phenomena which take place in the presence of a body which appears to be entirely unchanged by the action. Happily these catalytic actions are being explained one after another, so that soon the name itself may become obsolete. An example of this action of presence may be given. When a mixture of sulphuric acid and alcohol is heated to a temperature of about 140° to 150°, ether passes over. Now alcohol contains C_2H_6O, and if from two molecules of alcohol one molecule of water is subtracted a molecule of ether results :—$2C_2H_6O = OH_2 + C_4H_{10}O$. As sulphuric acid is known to have a great attraction for water, it is easy to imagine that the acid combines with the water and ether passes off. But it is found that a small quantity of sulphuric acid at the temperature of 140° – 150° will transform a very large amount of alcohol into ether and water, much more than can be explained by assuming that the acid has combined with the water. If a mixture of sulphuric acid and alcohol is heated to a temperature of 140° – 150°, and alcohol allowed to flow into the liquid, a mixture of ether and water vapours passes over, and after a large quantity of alcohol has been transformed, the amount of sulphuric acid is found to be unaltered. At first glance this seems very difficult to explain, but on further investigation it is found that alcohol and sulphuric acid act one on another to form ethyl-sulphuric or sulphovinic acid:—

$$SO_2Ho_2 + EtHo = SO_2HoEto + OH_2$$

but when ethyl-sulphuric acid is heated with alcohol, ether is formed with the reproduction of sulphuric acid—

$$SO_2HoEto + EtHo = OEt_2 + SO_2Ho_2$$

the sulphuric acid is then able to produce ethyl-sulphuric acid by acting on more alcohol, so a continuous production of ether and water takes place without loss of sulphuric acid. Another well-known action is the combination of oxygen and hydrogen under the influence of spongy platinum. In this case the platinum remains apparently unaltered, and is capable of causing the combination of any quantity of mixed gases. As spongy platinum possesses the power of absorbing large quantities of gases, it is usually said that the molecules of oxygen and hydrogen are so much condensed in the platinum that they are brought within the sphere of one another's attractions, and consequently combine.

Another instance of an action of this kind is afforded by the oxidation of ammonia in the presence of chromic oxide. When ammonic dichromate is heated an evolution of gas occurs, and a residue of chromic oxide is left which bears a striking resemblance to a mixture of black and green tea; when some of this substance is placed on a piece of wire gauze, heated and then supported over a vessel containing a strong solution of ammonia, the oxide glows in a manner similar to the glowing of spongy platinum under the influence of a mixture of hydrogen and air. Under these conditions the chromic oxide facilitates the oxidation of the ammonia, but it becomes changed during the process; instead of having the appearance above described, it acquires a bright green colour. Now, we know that chromium is capable of forming several combinations with oxygen. Is it therefore too much to suppose that the chromium is alternately oxidized by the oxygen of the air, and reduced by the hydrogen of the ammonia, so that, although in the end it has the same composition as at the beginning, nevertheless it has been continuously decomposed and reproduced? Now, may not a similar change take place during the action of spongy platinum on a mixture of hydrogen and oxygen? The alteration of the platinum is very slight, but I believe I have observed a slight modification of the appearance of a fragment of spongy platinum that was kept glowing by a small jet of purified hydrogen for some hours; the gas not being allowed to burn so as to heat the platinum to a very high temperature, the metal appears to be compacted and to be covered by minute spherules of glistening metal. Now, may not the platinum have entered into combination with one or other of the gases and been subsequently reduced? If this is the true explanation, then we have in this case a continuous series of chemical changes and the "catalysis" is explained.

We all know the ease with which oxygen is obtained from potassic chlorate when heated with a small quantity of oxide of manganese; the quantity of peroxide is the same at the end of the process as at the beginning, and it may be used over and over again to assist in the decomposition of fresh potassic chlorate. The oxide of manganese undergoes a molecular alteration; if a crystalline variety is employed, it is found, at the end of the process, to have been transformed into fine powder.

I hope I have proved to the satisfaction of my brother chemists that potassic permanganate is first formed and subsequently decomposed with the reproduction of manganese peroxide.

Oxide of cobalt possesses the remarkable property of decomposing solutions of hypochlorites at moderate temperatures with evolution of oxygen. For some time I have been endeavouring to find the explanation of the change, but hitherto without complete success. At first it seemed probable that an unstable cobaltate, analogous to a ferrate, was formed and decomposed at the temperature of the experiment. In fact oxygen is evolved when chlorine is passed through a boiling solution of sodic hydrate containing ferric hydrate in suspension. But no evidence of the existence of a cobaltate could be found. When a cobaltous salt is added to an alkaline solution of a hypochlorite, a black precipitate is formed which is usually stated to be cobaltic hydrate, Co_2Ho_6, but Vortmann has shown that, when a cobaltous salt is mixed with a solution of iodine in potassic iodide, and the liquid rendered alkaline by sodic hydrate, the precipitate formed at a temperature between 50° and 60° approaches in composition the dioxide of cobalt, CoO_2. He also found that the precipitate lost oxygen at the temperature of boiling water. I have repeated some of his experiments and can quite confirm them, although I have not obtained an oxide containing quite as much oxygen as his richest oxide. The oxides I prepared rapidly effected the decomposition of a solution of sodic hypochlorite, and that without undergoing any loss of oxygen themselves; in fact, in the two experiments made, the cobalt compound contained a little more oxygen after boiling with the hypochlorite.

We have now many instances of the influence which small quantities of substances have upon chemical reactions. These influences may be more common than is generally supposed. The presence of a third body is frequently helpful in the combination of elements with one another: thus dry chlorine will not attack melted sodium or finely divided copper; an electric spark will not cause a dry mixture of carbonic oxide and oxygen to explode; carbon, phosphorus, and sulphur will not unite with dry oxygen, and as chemical science progresses we may find that many well-known actions are conditioned by the presence of minute traces of other matter which have hitherto escaped detection. We all know the profound alterations of the properties of substances by minute traces of impurities; less than one-tenth per cent. of phosphorus will render steel unfit for certain purposes. The sapphire and ruby only differ from colourless alumina by the presence of traces of impurities hardly recognisable by chemical analysis. During this meeting we hope to have a contribution to the section on the influence of minute traces of what may be called impurities on the properties of different substances and their influence on chemical changes.

In this city, where the first public chemical laboratory was started in 1823, by Dr. Anderson, the assistant of Prof. Hope, it is hardly necessary to insist on the extreme importance of teaching chemistry by practical work, but unfortunately, even at the present time, endeavours are made to teach the subject by means of lectures (sometimes without experiments) or by reading. Those who are acquainted with chemistry well know the impossibility (this is hardly too strong a word) of learning the science, especially in the first stages, without actual experiment, by which a practical acquaintance with chemical phenomena is obtained. The attempt to learn chemistry without practical experience reminds one of the well-known story (for the truth of which I will not vouch) of a mathematician who lectured on natural philosophy; he was visiting a foreign laboratory, and stopped before a piece of apparatus and asked what it was: on being told it was an air-pump, he exclaimed, "Dear me! I have lectured on the air-pump for twenty-five years, and this is the first time I have seen one." It is problematical if his students can have derived much advantage from his lectures. Teaching of the kind to which reference has just been made is generally given to candidates for examinations who do not intend to take up chemistry as their chief subject. At the present time chemistry is required for entrance and preliminary examinations from many classes of students. There is no doubt that it is an excellent means of education, teaching a boy to observe and draw conclusions from his observations; but if he makes no observations it is little more than useless cram, the memory might as well be exercised by learning a novel by heart.

This imperfect mode of teaching chemistry arises principally from the difficulty of obtaining properly appointed laboratories in schools, in addition to which the very strong fumes are sometimes disagreeable, making it inconvenient to have them in or near a house, to say nothing of the possible dangers to the clothes and their contents; but there is no help for it, the teaching must be accompanied by experimental demonstration, as was indicated in the Reports on the teaching of chemistry which have been presented to this Association in former years. It must be admitted that examinations do not always discover the best student; many are capable of preparing for examinations with a small knowledge of their subject, others, with a good knowledge, fail from nervousness or other causes, but at the present time examination, though far from perfect, is almost the only means we have of judging the fitness of the candidate. By properly selecting questions the examiner may, to a considerable extent, discourage cram; he should endeavour to find out what the pupils have actually seen, and to make them draw conclusions from facts which they have either themselves observed, or which have been described to them; it is only in this manner that chemistry can be used as a means of mental training.

These remarks do not apply to the education of students intending to make chemistry their profession, who have many opportunities, in the large laboratories of Great Britain and the Continent, of obtaining all the necessary instruction. The Institute of Chemistry, which was founded to improve the status and also the education of professional chemists, requires that its members should have a thoroughly scientific training. Before a candidate for the associateship is admitted to examination, he must bring evidence that he has passed satisfactorily through a systematic course of at least three years' study in the subjects of theoretical and practical chemistry, physics, and elementary mathematics, in some recognized college or school; and before admission to the fellowship he must have passed through three additional years of work in chemistry. It is to be hoped that an example of this kind will ultimately have a good effect in improving the modes of teaching the science in its elementary stages.

There is another class of workers in chemistry who must not be forgotten at the present time, as they have much influence on the life of the world and have been working for ages, but have only recently been recognized. I mean those organisms which are included under the name of microbes. These organisms are capable of producing chemical changes which entirely surpass all the results hitherto obtained by the chemist in his laboratory. That the transformation of sugar into alcohol and carbonic anhydride in the ordinary process of fermentation is due to a living organism, has been known for some years; the important transformation of ammonia into nitrous and nitric acids in the soil has been shown to be due to organisms which have recently been investigated by many chemists; it is possible to transform ammonia into these acids in the laboratory by oxidation under certain conditions and at a high temperature, whereas the organism does the work quite as efficaciously at the common temperature. Other organisms have the power of producing complex organic poisons by the alteration of some of the constituents of the animal body, and the relation of these products to the study of diseases is of the highest possible importance. As we hope to have a discussion on this interesting subject by many eminent authorities, both from the chemical and biological points of view, it will be unnecessary to pursue the subject further, unless it be to urge some of the younger chemists to work at the chemical aspect of bacteriology. They must be prepared for hard work and many disappointments, for the subject is undoubtedly a difficult one.

I cannot conclude this address without reference to the great loss which chemistry has sustained by the death of Prof. A. W. von Hofmann. I had the good fortune to be under him as student and assistant from 1856 until he left this country in 1865; all who worked with him must have been deeply impressed by his capacity for work and his power of inducing work in others. Although perhaps some of us did not appreciate this at the time, yet we feel we owe him a debt of gratitude for his having started us in the right way. The list of papers under his name in the Royal Society Catalogue up the year 1883 is 299, written by himself alone, besides twenty-two joint papers. One of his characteristics which impressed me was his investigation for the purpose of furthering chemical knowledge without any view to practical applications, and I well remember his lecture at the Royal Institution, in 1862, on Mauve and Magenta (which owed so much of their success to his work), in which he produced the original specimen of benzene which had been obtained by Faraday from oil-gas in 1825. He pointed out that Faraday had prepared this substance and investigated its properties without ever supposing that it could have any practical application. The following is the concluding paragraph of the lecture:—

"Need I say any more? The moral of Mauve and Magenta is transparent enough; I read it in your eyes. We understand each other. Whenever in future one of your chemical friends, full of enthusiasm, exhibits and explains to you his newly-discovered compounds, you will not cool his noble ardour by asking him that most terrible of all questions, 'What is its use? Will your compound bleach or dye? Will it shave? May it be used as a substitute for leather?' Let him quietly go on with his work. The dye, the lather, the leather will make their appearance in due time. Let him, I repeat, perform his task. Let him indulge in the pursuit of truth—of truth pure and simple—of truth not for the sake of Mauve, not for the sake of Magenta, let him pursue truth for the sake of truth."

This seems to me the true spirit of the scientific investigator and in many cases the reward consists solely in the consciousness that the investigator has done his duty; in some cases the reward may take a more substantial form, and since the above paragraphs were written I have been informed that Prof. von Hofmann has left a large fortune, the result of the applications of his discoveries in technical chemistry.

NOTES.

WE hope to publish shortly, in the series of "Scientific Worthies," a portrait of Sir Archibald Geikie, whose address as president of the British Association we print to-day. The portrait will be accompanied by a sketch of Sir Archibald's career as a man of science.

THE International Congress of Experimental Psychology began work at University College, Gower Street, on Monday, when an address was delivered by Prof. H. Sidgwick. We propose to give on a future occasion some account of the proceedings.

THE Helvetic Society of the Natural Sciences will hold its seventy-fifth annual meeting at Basel from September 5 to 7. The Basel Society of the Natural Sciences will celebrate its seventy-fifth anniversary at the same time.

MR. J. BRETLAND FARMER, M.A., Fellow of Magdalen College, Oxford, and Demonstrator of Botany in the University, has been appointed Assistant-Professor in Botany at the Royal College of Science, London, as successor to Dr. D. H. Scott, who becomes Honorary Keeper of the Jodrell Laboratory, at the Royal Gardens, Kew.

MR. H. M. BERNARD, M.A., has been elected to the Marshall Scholarship, Royal College of Science, South Kensington, for the ensuing year, in place of Mr. G. Biebner, whose term of office has expired.

MR. J. P. HILL, of the Royal College of Science, South Kensington, and the University of Edinburgh, has been appointed to the Demonstratorship of Biology in the University of Sydney.

MR. SILVA WHITE has, for reasons of health, resigned his office as secretary and editor to the Royal Scottish Geographical Society, a post he has filled since the institution of the society.

WE regret very much to hear of the death of Dr. H. J. Tylden, whose article on "The bearing of pathology upon the doctrine of the transmission of acquired characters" was printed in NATURE last week. At the beginning of last week he died of typhoid fever. Dr. Tylden had been engaged in investigating the etiology of typhoid fever, and there is no doubt that he thus contracted the disease.

TWO eminent men who had been intimately connected with India died last week—Dr. Forbes Watson and Dr. H. W. Bellew. Dr. Bellew was well known as an Oriental linguist and as the author of various works in which he made important contributions to ethnology. Dr. Forbes Watson acted for many years as Reporter on the Products of India and Director of the India Museum. He did much to give the English people a wider and more accurate knowledge both of the races and the material resources of India.

THE death of Dr. Felice Giordano, of Rome, is announced. He was the head of the Geological Survey of Italy and Chief Inspector of Mines.

THE Glasgow and West of Scotland Technical College has issued its calendar for the year 1892-93.

ON July 27 the eruption of Mount Etna, which on the previous day had increased considerably in activity, was again as violent as during the first few days of the outbreak. Rocks and masses of volcanic *débris* were ejected from the crater to a great height, as well as a quantity of fine ash, which fell in showers over the country. The cloud of smoke over the summit increased, and the subterranean rumblings were so loud and frequent as to make the windows in the houses rattle. The lava streams were also extending. Similar reports were issued on the three following days; but on July 31 a general decrease in the volume of the lava was noted. On August 1 it was stated that the eruption seemed to be subsiding. No underground rumblings were heard, the smoke issuing from the crater was white, and the lava streams moved very slowly, and, in fact, almost stopped. On August 2 the volcano showed some signs of renewed activity, and the lava streams began to flow afresh. The underground rumblings were not, however, so loud as before.

SOME information as to the volcanic eruption in Great Sangir is given in letters sent from Menado, the chief Dutch settlement in the north of the Celebes, from which Sangir is about 300 miles distant. The letters are dated June 12, and were printed in the *Handelsblad*, of Amsterdam, on July 27. According to a summary in a Reuter's telegram, the disaster came with appalling suddenness. At ten minutes past six on the evening of June 7, unannounced by the slightest shock of earthquake, subterranean rumblings, or other seismic warning, a terrific eruption began from the great volcano Gunona Awa, which is not far from Tarvena, the capital of the island. Ashes in immense masses and stones of considerable size soon fell all over the island. Hundreds were killed by this shower, and even those who reached the shelter of their homes were not safe, for nearly everywhere in the country districts the light wooden houses collapsed under the weight of the stones and ashes which quickly settled on the roofs. In the immediate vicinity of the mountain, on the slopes of which are numerous farms and villages with extensive plantations, immense destruction was caused by the great streams of lava, which flowed with astonishing rapidity down into the surrounding valleys. Houses were carried away with all their contents, and many of the occupants met a terrible death in these rivers of molten rock. Besides the hundreds who are known to have lost their lives on the lowlands, between five hundred and a thousand more who were engaged in the rice-fields on the mountain slopes have not been heard from. The crops have been destroyed, the cocoa-nut trees have suffered severely, and in many parts of the island the wells have become dry.

AT the time of our last issue the weather was very settled, and the air very dry, scarcely any rain having fallen for some days. On Friday, however, July 29, the anticyclone began to give way, and the low pressure over the Bay of Biscay extended northwards and over the eastern parts of England, causing thunderstorms in the southern counties. By Sunday, the disturbed weather had extended over the whole country, and rain had fallen at most places, but the area of low barometer was passing away to the eastward, and during the early part of this week the type of weather again became anticyclonic generally, but the sky became cloudy, and rain fell in places; while on Wednesday a depression lay over the North of Scotland, which appeared likely to spread southwards. Temperatures have ranged from 70° to 75° and upwards in the southern districts, but have been considerably lower in the north; the daily maxima frequently not reaching 60°. The *Weekly Weather Report* showed that for the week ending July 30 the temperature only slightly exceeded the average in the North of Scotland. Rainfall was much below the mean, amounting to six to nine-tenths of an inch in most districts, while reckoning from the beginning of the year there is a deficit in every district, amounting to as much as 7·4 inches in the south-west of England.

THE Austrian Meteorological Society has issued an appeal for contributions towards the support of the meteorological observatory on the summit of the Sonnblick. The observatory was established by M. Rojacher in 1886, and completed at the expense of the Austrian Society and the German and Austrian Alpine Club; it has since been maintained at the expense of these two institutions, together with a subvention from the Ministry of Instruction, and aided by a small reserve from the original building fund. The recent death of M Rojacher, and the removal of the Alpine Club from a house on the summit, has thrown such additional expense on the Austrian Society as to endanger the efficient maintenance of the Observatory. The station has already rendered good service to science and has somewhat modified the theory of the nature and origin of storms; several physicists have also conducted experiments there on radiation, atmospheric electricity, and other subjects of considerable importance. We hope, therefore, that the appeal of the Society for funds for the efficient maintenance of the station will meet with entire success.

THE trustees of the South African Museum, in their report for the year 1891, record a serious loss in the mineralogical series of the Museum's collection. On the night of September 7 and 8 the Museum was robbed of the Stonestreet collection of rough diamonds, a separate diamond in singularly hard rock, and several very interesting nuggets of South African gold. The exhibition hall was broken into through one of the small upper windows opening on the higher of the two galleries, and the specially protected table-case, containing the diamonds and gold, forced by shattering the lock. Two men—whose names, A. McEwen and E. Cohen respectively, were already too well known in the criminal records—were convicted of the robbery at the Supreme Court session on the 13th November, and sentenced to four years' hard labour. The police succeeded in recovering 49 of the 173 diamonds belonging to the Stonestreet collection, including most of the larger stones, but among the missing majority are many unusual and abnormal crystalline forms of much interest, collected with great pains by the late Mr. Stonestreet, during the earlier years of mining in Griqualand West. The Du Toit's Pan diamond in indurated rock and the gold nuggets have not been recovered.

IN the course of an interesting address delivered lately at the opening of the new chemical laboratory of the Case School of Applied Science, Prof. C. F. Mabery called attention to the fact that notwithstanding America's abundant supply of crude materials, with cheap fuel in unlimited quantities, and a ready market with an increasing demand, she continues to pay enormous sums for imported products which should be produced at home. Prof. Mabery thinks, however, that the outlook for the immediate future is encouraging. In several directions the manufacture of chemical products has begun, and others, he believes, will follow. There are certain lines along which rapid development may evidently soon be expected, and one of the most promising is sal-soda. Until quite recently the Le Blanc process, which was invented in France to manufacture soda-ash when the supply from natural sources was largely cut off during the French Revolution, has supplied the world since early in the present century. In utilizing all bye-products the great Le Blanc works of Europe have been able to produce soda-ash at a trifling cost. A Le Blanc plant has never been established in America, and probably one never will be. Such a plant requires immense capital, and, besides, a combination of coal, salt, and limestone, that can be found close at hand in but few localities. Within a few years another method, known as the ammonia-soda process, has been put into operation in Europe. The first cost of a plant for this process is not large, and since it furnishes a purer product than the Le Blanc method, it will probably supply a considerable portion of the sal-soda of the future, especially in the United States. The newer method has the especial advantage that it forms bicarbonate of soda direct and very pure. Two plants for this process have been erected in America, one of which has been in operation at Syracuse, N.Y., for several years, and the other has recently been erected in Cleveland. As additional illustrations of the possibilities in store for the United States, Prof. Mabery mentioned the manufacture of porcelain, and the production of artificial dyes and colours from coal-tar.

AN interesting report on the pearl fishery of the Gulf of California is contributed by Mr. C. H. Townsend to the new Bulletin of the United States Fish Commission. The season for pearl fishing begins about the first part of May near Cape St. Lucas, whence operations are gradually carried into the Gulf of California, which is usually entered by May 15. During the summer the entire eastern coast of the peninsula is worked, and in October the base of operations is removed from La Paz, the headquarters of the Pearl Shell Company of Lower California, to Acapulco, where the fishery is continued for two or three months longer. Whatever of romance may hitherto have enshrouded the diver for pearls in the sea, he is now, as described by Mr. Townsend, practically a submarine labourer, who uses all the modern diving paraphernalia available. No longer plunging for sixty seconds into the sun-lit green water that covers a coral bank, he puts on a rubber suit with glass-fronted helmet, and, suitably weighted with lead, descends for hours to gather pearl-oysters, which are hoisted in a wire basket by his companions in the boat above, who supply him through a rubber tube with the air he breathes. The best year at the fisheries in comparatively recent times was 1881. During that year many pearls of extraordinary size and great value were obtained; among them was a black one weighing twenty-eight carats, which sold in Paris for 10,000 dollars.

A VALUABLE report on the petroleum trade of the Caucasus has been sent to the Turkish Government by Aassib, the Turkish Consul-General at Tiflis, and some interesting extracts from it are quoted in the *Board of Trade Journal*. The petroleum springs of the peninsula of Apcheron, not far from the place at present occupied by the town of Baku, were known according to the writer, several centuries before the Christian era, and the phenomena produced by them, totally inexplicable in those barbaric ages, gave rise, he says, to the worship of the Guebres, followers of Zoroaster, which lasted into the nineteenth century, for the temple of the worshippers of eternal fire is seen to the present day. The springs of Balakhani are situated 20 kilometres from Baku on a bare and arid plateau, swept by the winds, at an elevation of about 60 metres above the level of the Caspian Sea. The petroleum lands occupy an area of about 8 kilometres. At the present time Balakhani and Sabountchi possess more than 1000 wells, some of them newly bored, producing in twenty-four hours as much as 400,000 pouds. An era was marked in the history of the naphtha industry by the house of M. Nobel, which started at Baku in 1874, and in the following year purchased a small business and undertook the production of petroleum on a small scale. At that time the conveyance of petroleum to Baku was effected by means of carts and leather bottles. M. Nobel endeavoured to show the absurdity of this primitive method of transport, and recommended that pipes should be constructed, but the majority of the merchants rejected the proposal. He then constructed the first pipe at his own cost, and demonstrated the utility of it to his colleagues, several of whom very soon imitated his example, and Baku has to-day a dozen lines of pipes, each of which costs more than 100,000 roubles. The same house, dissatisfied with the system of shipping petroleum in barrels, proposed to the Kavkaz and Mercury Navigation Company of the Caspian and the Volga that they should build tank boats for the exclusive conveyance of petroleum. This proposal having been rejected, the firm constructed several of these vessels at their own expense. This innovation, of which even the Americans had not yet thought, was accepted by the two petroleum-producing countries, and tank boats, the number of which is constantly increasing, are to be found on all the waters of the civilized world. It is also to M. Nobel that those gigantic reservoirs of iron which contain hundreds of thousands of naphtha products are due. They are to be seen in large numbers at Baku, Batoum, and everywhere else where petroleum is carried in bulk. The series of innovations by M. Nobel do not stop there. With a desire to improve land carriage he proposed to the Griazi-Tsaritsine Railway Company the construction of special tank waggons for the transport of the petroleum, guaranteeing a load for them for several years. The railway authorities scoffed at the idea, and it was by the expenditure of very large sums that the Swedish merchant constructed for his own use the first tank waggons. Scorn was immediately changed to enthusiasm, and to-day thousands of these waggons circulate on the railways of Caucasia and Griazi Tsaritsine.

IN Part xxi. of the Zoological Reports of the Norwegian North Atlantic Expedition, Christiania, 1892, Dr. D. C. Danielssen gives an account of the Crinoids and Echinoids of the North Atlantic. Chief among the former is the beautiful *Bathycrimus carpenteri*, first described as *Ilycrinus carpenteri* by Koren and Danielssen in 1877 from specimens collected by the expedition, and thought to be a new genus, but a careful study and comparison with Herbert Carpenter's description in the report of the *Challenger* Crinoids proved it to belong to *Bathycrinus*. The morphology of this species is very fully described and figured; very interesting are the statements about the apparent formation of "new crown" on specimens which had apparently lost their first crowns; in one of these "the stalk was 110 mm. in height, the crown was 2·5 mm. high, and the root was 20 mm. in length. The radials of the crown were attached to the basals by a pretty broad seam, the basals being concreted and forming a firm ring as upon old individuals; which distinctly showed that while the radials were a new formation, the basals pertained to the old detached crown and formed the true calyx from which the new crown issued." In this specimen the tentacles could not be seen, and it was very difficult to observe the disc, as it was covered by the closed arms which could not without damage be separated from each other, but that a new crown was in course of formation seemed indubitable. In addition to this species of Bathycrinus, *Rhizocrinus lofotensis*, and the following species of Antedon were found:—*A. tenella*, Retzius; *A. petasus*, D. and K.; *A. prolixa*, Dun. and Sladen; *A. quadrata*, Carp.; and *A. eschrichti*, Muller. Fourteen species of Echinida are mentioned, of which *Echinus alexandri*, Dan. and Kor., is redescribed and figured.

THE additions to the Zoological Society's Gardens during the past week include a Hainan Gibbon (*Hylobates hainanus*) from Southern China, presented by Mr. Julius Newman; a Humboldt's Lagothrix (*Lagothrix humboldti*) from the Upper Amazons, presented by Mr. Chas. Clifton Decconson, F.Z.S.; a Red Howler (*Mycetes seniculus*) from New Granada, presented by Mr. John F. Chittenden, C.M.Z.S.; a Garnett's Galago (*Galago garnetti*) from East Africa, presented by Commander H. J. Keene, R.N.; a Bennett's Wallaby (*Halmaturus bennettii* ♂) from Tasmania, presented by Lieutenant E. A. Findlay, R.N.R.; a Raccoon (*Procyon lotor*) from North America, presented by Mr. A. C. Cooke; a Short-toed Eagle (*Circaetus gallicus*) from Southern Europe, presented by Mr. B. Vincent; a Leadbeater's Cockatoo (*Cacatua leadbeateri*), a Slender-billed Cockatoo (*Licmetis tenuirostris*) from Australia, presented by Mrs. Phillips; a Rock Thrush (*Monticola saxatilis*), two Solitary Thrushes (*Monticola cyanus*), European; a Common Jay

(*Garrulus glandarius*), an Ortolan Bunting (*Emberiza hortulana*), a Blackbird (*Turdus merula*), a Nightingale (*Daulias luscinia*), British, presented by Mr. E. Cossavella; a Common Jay (*Garrulus glandarius*), a Natterjack Toad (*Bufo calamita*), six Crested Newts (*Molge cristata*), three Palmated Newts (*Molge palmata*), British; three Sand Lizards (*Lacerta agilis*), five Yellow-bellied Toads (*Bombinator bombinus*), an Edible Frog (*Rana esculenta*), European, presented by Mr. G. B. Coleman; four Common Snakes (*Tropidonotus natrix*), British, presented by Count Pavoleri, F.Z.S.; a Malbrouck Monkey (*Cercopithecus cynosurus*) from West Africa, a Barbary Wild Sheep (*Ovis tragelaphus ♂*) from North Africa, two Common Squirrels (*Sciurus vulgaris*), British, deposited; two black Apes (*Cynopithecus niger*) from Celebes, purchased.

OUR ASTRONOMICAL COLUMN.

Solar Observations at the R. Osservatorio del Collegio Romano.—Prof. Tacchini, in the *Memorie della Società degli Spettroscopisti Italiani*, gives a tabular statement of the prominences, faculæ, and spots visible on the sun's surface during the first three months of the present year. Taking the case of the number of prominences, no less than 300 were observed during this period, 161 appearng in northern and 139 in southern latitudes. During the first two months prominences were more numerable in the south hemisphere, amounting to an excess of 7 and 5 respectively, but in March as many as 78 were recorded for the northern as against 44 for the southern. The latitudes for the regions of greatest frequency were + 40° + 30° and − 20° − 30°.

For the faculæ 28, 24, and 18 (total 70) were recorded for the northern latitudes, while very nearly the same number (76 = 20 + 18 + 38) was observed on the southern hemisphere. In both cases the record for latitudes ± 50° ± 40° was one, the greatest number appearing in latitudes ± 10° ± 30°.

The total number of groups of spots recorded was 80, of which 38 were observed north of the equator. Curiously enough the month of February only contributed 21 out of this number, 34 being recorded for January; the region of greatest frequency occupied the zones ± 10° ± 30°.

Allowing for the very unfavourable season for observations, a considerable increase over the preceding quarter will be at once noticed. The relative amount of spotted area shows an enormous increase for February, the numbers for the months commencing with January being 79.79, 153.61, and 61.57.

A Remarkable Prominence.—Mr. J. Fényi, in the *Memorie della Società degli Spettroscopisti Italiani*, gives an account of an unusually large prominence that was visible at Kalocsa, on May 5 last. At 10h. 25m., Kalocsa mean time, the prominence was very small, but later it developed very considerably, forming itself into a set of small bands, clearly inclined towards the equator. At 11h. 55m. the observed height was 139″, there being no indication of a rapid ascent. At 12h. 11m. a very rapid upward motion had already begun to make itself visible, and by 12h. 17m. 34s. the height reached was 287″, extending to 317″ 1m. 11s. later, when the velocity of ascent was 306 km. per second. After a few minutes the lower parts to the height of 360″ became invisible, but the smooth portions ascended at 12h. 21m. 4s., with a velocity of 368 km. per second to a height of 531″. This latter measurement was made at 12h. 29m. 25s., and soon after the object was no more seen. The actual height attained, then, may be reckoned about 381,800 km., or 237,126 miles. At the terminaton of this eruption, it was noticed that the prominences at 127° and 79°, and even the one at 106°, which very nearly coincided with the position of the eruption itself, still retained the same forms, having apparently suffered no change by this enormous disturbance; no faculæ or spots either were recorded which could in any way be connected with this outbreak.

The Trapezium in the Orion Nebula.—During the first three months of the present and preceding year Dr. L. Ambronn, of the Göttingen Observatory, has undertaken a measurement of the distances and position angles between the four bright stars forming the trapezium in the great nebula of Orion. The results which he has obtained are recorded in the 3103 number of *Astronomische Nachrichten*.

Commencing with the star θ′ Orionis, which is here designated *a*, and taking the others in cyclic order following the direction opposite to that of the motion of the hands of a watch, we find these designated by *b*, *d*, and *c* respectively. The accompanying table, for the sake of comparison, shows the position angles and distances for the equinox 1870 from the measurements of W. Struve, Dembowski, O. Struve, Hall, and Ambronn.

	W. Struve. 1836·15	Dembowski. 1867·04.	O. Struve. 1870·0.	Hall. 1877·7.	Ambronn. 1891 6.

New Variable Stars.—A short note communicated by Prof. Pickering to *Astronomische Nachrichten*, No. 3104, informs us that six new variable stars in the southern sky have been discovered on examination of the photographs of stellar spectra taken at Arequipa in Peru. The following are the constellations, positions, and the dates on which the photographs were taken:—

Constell.	α 1900 h. m.	δ 1900 ° ′	Date.
Horologium ...	... 2 49·5 ...	− 50 10 ...	Sept. 10, 1891
Octans ...	... 6 0 ...	− 86 30 ...	Sept. 11, 1891
Bootes ...	... 14 22·1 ...	+ 5 2 ...	April 26, 1892
Octans ...	... 17 30 ...	− 86 45 ...	Aug. 31, 1891
Sagittarius	... 19 49·8 ...	− 29 27 ...	Oct. 3, 1891
Tucana ...	... 23 53·2 ...	− 65 56 ..	Aug. 25, 1891

All these stars when at a maximum are as bright or brighter than the 8th magnitude, but only one, that in Sagittarius, is a catalogue star (Cord. G.C. 27271, Mag. 8½).

THE BRITISH ASSOCIATION COMMITTEE ON ELECTRICAL STANDARDS.

In view of the hoped-for presence of Prof. von Helmholtz and other distinguished foreigners at this year's meeting of the British Association in Edinburgh, it will probably be recognized as suitable to take up and continue the discussion on new electromagnetic units for practical purposes, which was begun last year at Cardiff.

I therefore beg to contribute the following notes and to conclude by moving some resolutions.

One great fact brought into prominence by the practical development of electricity is the analogy or reciprocity between the electric and the magnetic circuit, and this is the fact which it behoves us to emphasize in the naming of fresh units.

The magnetic circuit has as yet no authorized names applied to it. The electric circuit is well provided, but perhaps one or two improvements can be made.

(1) The Electric Circuit.

The first point on which I consider that practical men would do well to insist is that names shall be given to the complete things dealt with, rather than to mere coefficients. Thus of all units with which they are concerned there can be no doubt but that *volt* and *ampere* are the most prominent. These are the active things with which Electrical Engineers have to deal, and these are the things for which meters exist on every wall in an electric lighting station. The ohm, or unit coefficient of resistance, is comparatively academic in character; it is a constant of a coil of wire or of an underground lead, it is nothing vivid and active. The engineering use of the term ohm is mainly in connection with insulation and other high resistances; for large conductors the equivalent "volt per ampere" is perhaps more often used. It is the drop of potential which a given conductor entails for a given current that is of real interest to an engineer, and it is this of which in large leads he consciously thinks.

A 6 ohm conductor means one that drops 6 volts for every ampere that is sent along it. If you send 3 amperes along such a line, the potential at the far end is 18 volts below that at the near end. The clear realization of this fact would be almost aided by the complete title, 6 volts per ampere, instead of the abbreviation, 6 ohms. Nevertheless, the name ohm is in common use and hence may be assumed useful.

A still more useful name, however, for good conductors would really be the reciprocal of an ohm—the ampere per volt. Suppose this called a mo, as Sir W. Thomson once suggested, then a cable of 20 mos would be one that conveyed 20 amperes with a drop of 1 volt. A thousand-mo cable would convey 500 amperes with a drop of half a volt, and so on. It is more directly practical to think of the amperes conveyed per drop of voltage, than of the drop of voltage per ampere. I believe that some authorized name for unit conductance would be welcomed.

Units of Inconvenient Size.

The authorized name "coulomb" for unit quantity is barely used by engineers, who are content with ampere-hour; thus proving that what is needed in practical units is not so much a consistent decimal system, as a set of units each of practicable magnitude.

Farad.

The effort after consistency has resulted in the useless "Farad"; and this should be a lesson not to try and fix units of unreasonable size. The c.g.s. units already exist as a consistent system; the only objection to them is that they are of unpractical size. The whole object of devising a practical system of units was to have things of every-day size to deal with. The volt, the ampere, and the ohm satisfy this condition. The coulomb, the farad, and the watt do not. Already they have practically given place to the ampere-hour, the micro-farad, and the kilowatt.

Considerably more progress would have been made in knowledge of ordinary capacities if the microfarad had been called the farad, so that easy submultiples of it would have been available to express the capacity of Leyden jars, and such like things. The capacity of an ordinary jar would then have been a few millifarads, and a microfarad would have been the capacity of a short bit of connecting wire. I ask whether this change would introduce serious confusion even now. I think not. Nobody cares the least about "coulombs per volt," and so there is no sense or use in the present farad. Telegraphists would surely soon consent to drop the useless prefix micro; and the factor of a million is too great to render doubt possible as to what was intended, even in the transition stage. It ought to be regarded as essential to have the practical unit somewhere not hopelessly away from the middle of the range of probable multiples and submultiples.

Coulomb.

A coulomb again is almost useless as a synonym for the ampere-second; it is so easy to speak of ampere-minutes or ampere-hours. If the name coulomb could be set free from its present superfluous meaning it could usefully be applied to the electrostatic unit of quantity, which wants a name. Teachers would find it convenient at once, and in the apparently imminent line of development engineers might find it useful before long. It is the charge on a two-centimetre sphere at a potential 300 volts (or on a one-foot sphere at 20 volts). The capacity of the two-centimetre sphere would be $\frac{9}{10}$ of a (new) microfarad.

Watt.

Lastly with regard to the watt. The name volt-ampere is almost as good as the name watt, especially since the watt is also one joule per second.

Both names, watt and joule, are not really wanted by electricians, to whom their coexistence is rather confusing. I believe it would be more convenient to use the term watt in the sense it gets so frequently used now, viz., energy, say a volt-ampere-hour; in which case a kilowatt would be synonymous with the present Board of Trade unit.

The rate of working, or power, could then be expressed in a rational and unforced way as so many watts per hour or so many volt-amperes. It is much more natural to give a name to a definite thing like a quantity of energy, than it is to give it to a mere rate of working. The latter is instinctively felt to need a reference to time; just as a velocity unit has not been practically found to need a name, being quite simply expressible in feet per second or miles per hour; and even when a name has been given, like "knot," instinct constrains people to practically get rid of it again by speaking of knots per hour, just as we find "kilowatts per hour" already often used in electrical workshops. I suggest, therefore, that the present watt is too small, that it is sufficiently expressed by a joule per second, and that it would be more useful if magnified 3,600 times, and turned into a unit of energy.

That we should thus have several energy units—the erg, the joule, and the watt, all of quite different sizes, is no objection, but an advantage, seeing the extreme importance of energy. Such things as length, mass, time, and energy demand a fair range of units. It would be tedious to express centuries in seconds.

(2) MAGNETIC CIRCUIT.

In speaking of the magnetic circuit I wish to refer back to my opening remarks concerning the electric circuit, and the class of things for which names should be found. In the magnetic circuit the only thing at present seriously attempted to be named is, in accordance with the historic parallel of the ohm, a coefficient or characteristic of a coil of wire—its coefficient of self-induction; the unit of which has been called variously a secohm, a quadrant, and a henry.

Total Induction.

But the real active thing with which engineers are concerned is total magnetic induction, total number of lines of force across an airgap: as between the polepieces or through the armature of a dynamo, or in the circuit of a transformer. It may be called the electromagnetic momentum per turn of wire; or the surface integral of B. This total induction is in some respects analogous to electric current, and has occasionally been called magnetic current (a bad name), or "magnetic flux." It is, however, more strictly analogous to the coulomb, and its time rate of variation is the more proper representative of electric current.

Its common practical name at present is "total lines," or "total induction," or "number of lines."

Now "one line" is awkward as a unit, besides being (if a c.g.s. line) inconveniently small. The earth, for instance, sends 4,400 such lines through every horizontal square metre about England; through a square inch it only sends a fraction of a line. A practically sized unit of induction badly wants a name, and "henry" would have done for it very well, and have been both more suitable and more useful for the actual quantity than for a coefficient. But "henry" has already been half appropriated to the secohm, so, for illustrative purposes at any rate, I propose to use the name "weber" for the unit magnetic flux.

Concerning the most convenient size for the weber, there is much to be said for making it 10^8 c.g.s. lines, though that is bigger than ordinarily occurs in practice; because then a wire which cuts one weber per second will have a volt difference of potential between its ends. Or a coil of twenty turns through which the magnetic induction changes at the rate of one weber per second will have an E.M.F. of twenty volts induced in it. The average E.M.F. in such a coil, spinning thirty turns a second, and enclosing a maximum total-induction of one weber, is 600 volts.

This is the dynamo use of the unit; the following is the motor use.

A wire carrying an ampere and cutting a weber per second, does work at unit rate, viz., one joule per second.

Probably the simplicity of all this compensates for the rather unwieldy size of the unit. A strongly magnetized piece of iron may have 20,000 lines to the square centimetre; so a weber could occur across a narrow airgap half a square metre in area.

The earth gives an induction of about one weber through every 23,000 square metres of England, or 100 webers per square mile. The earth induction through a horizontal square metre is 44 micro-webers, so with micro- and milli-webers the range would be fairly covered; though a smaller weber would have been better if it had been equally convenient as regards the volt.

The pull between two parallel surfaces joined by a weber is $\frac{10^{16}}{8\pi}$ dynes, or four hundred thousand tons. A milli-weber gives less than half a ton pull; and a micro-weber less than half a gramme.

Because of the property that the voltage excited in a circuit is equal to the webers cut by it per second, a weber might be called a sec-volt. It is equal to a secohm-ampere-turn; that is to say, if a single turn of wire can have a self-induction coefficient of one secohm, it will excite a weber of induction for every ampere passing through it.

[Such a circuit in the form of an anchor ring would be enormous, something like a mile across; but it could be made in the form of a solid cylinder of best iron ($\mu = 2500$), with an axial perforation for the wire, and 80 metres long.

If a secohm coil has n turns, then an ampere passing through it excites only $\frac{1}{n}$th of a weber; for, since every turn encloses the induction, the latter is effective n times over, and so the induction coefficient is n times the induction per ampere, or n^2 times the induction per ampere turn.]

No name is needed for intensity (or density) of induction (B), for that can always be expressed in webers per unit area.

[For instance, strongly magnetized iron, with say 10,000 lines to the square centimetre, has one-tenth of a weber per square foot, or 0·7 milli-webers per square inch.]

And there is a practical gain in thus leaving the specification of area open, for it enables British units of length to be employed in measuring air-gaps, yokes, cores, and polepieces.

So long as dynamo dimensions are commonly expressed in inches, there is no serious objection to specifying induction in fractions of a weber per square inch or per square foot.

Magnetomotive Force.

Now consider the magnetic analogue of the volt; the unit of magnetic potential or magnetomotive force. By this is understood the line integral of the magnetizing force H, the quantity $4\pi n\mathrm{C}$, the step of potential once through and all round the circuit of a coil. It is a quantity most important in practice, and requires a name.

Mr. Heaviside has suggested the name "gaussage," as analogous to voltage; and, if this were adopted, the unit of magnetomotive force would be the gauss. The intensity of magnetizing force would be the gauss-gradient, or drop of gaussage per centimetre; no special name is needed for the unit of this quantity H.

The common practical unit of gaussage at present is the ampere-turn, and this has several advantages. It may, however, be found better to make some convenient number of ampere-turns into a gauss; for instance, the c.g.s. unit of gaussage would be $\frac{4\pi}{10}$ or 1·2566 ampere-turns. If that were adopted as the gauss, the horizontal component of the earth's magnetic intensity about here would be, say ·18 gauss per linear centimetre.

But this unit, whether the c.g.s. unit or the ampere-turn, is very small. The step of potential all round a single ampere-turn is only equivalent to a vertical step of about 2 centimetres in the earth's field.

Nevertheless, in spite of its smallness, the ampere-turn as practical unit of gaussage will probably commend itself by reason of its simplicity. Let us see how it works out.

Reluctance.

The ratio of gaussage to the induction excited by it, is a quantity characteristic of the magnetic circuit, and called its reluctance or magnetic resistance. This is the quantity $\frac{l}{\mathrm{A}\mu}$ for simple circuits, or $\Sigma\frac{l}{\mathrm{A}\mu}$ for complex ones; it is unfortunately not constant for any but air circuits. This constitutes one difficulty of naming its unit satisfactorily, else it might be expressed as so many "gilberts" or "sturgeons" (analogous to ohms). It is, however, fairly constant under many common conditions of practice, and it can always be expressed as gausses per weber; and perhaps this way is sufficient.

A magnetic circuit with unit reluctance is one that requires one gauss to induce in it one weber.

Permeability.

Permeability (μ), analogous to electric conductivity, would be measured by the webers induced through unit cube of the material between whose faces there is unit fall of gaussage. It has been suggested (by Prof. Perry) that the permeability of air had better be called $4\pi \times 10^{-9}$. But the whole electromagnetic system of units is based on the μ for air being called 1; so it would be rather confusing to change that. Moreover, it would be a retrograde step to affix another incorrect value to the constant μ, instead of waiting and trying to find out what its value really is. It is better to adhere for the present to the existing table of permeabilities, and to use whatever constant factor may be needed in order to turn $\frac{l}{\mu\mathrm{A}}$ into practical units of reluctance.

Permeance.

But the reciprocal of reluctance, or the webers induced per gauss, may be the more instructive thing to attend to and name; just as conductivity is often more directly interesting than resistance. This reciprocal ratio, $\frac{\mu\mathrm{A}}{l}$, has been called "permeance," and that is not a bad name for it; it is proportional to the inductance of a single-looped circuit. Permeability is the permeance of unit cube of the material. Permeance is the webers induced per unit drop of gaussage. Permeability is the webers per unit area induced by unit gauss gradient.

The permeance of the magnetic circuit enclosed by a solenoid of wire is the same as its appropriate self-induction-coefficient divided by 4π times the square of its number of turns.

The c.g.s. unit of permeance (or of reluctance) is that of a centimetre cube of air, and is not a bad-sized unit. But it is inconsistent with the weber as 10^8 and the gauss as a single ampere turn.

One of the three must give way.

On the whole I have no hesitation in suggesting that the derived unit (that of permeance) must give way, and be taken as $4\pi \times 10^7$ c.g.s. units, in order to harmonize with the other two as already defined.

The fact is that the great size of the weber renders a small gauss desirable, in order that their product may not represent too large a quantity of energy. For instance, if 1 c.g.s. unit were taken as the unit of permeance, the weber being fixed at 10^8, then the gauss would also be 10^8, and the gauss-weber would be 10^9 joules, or nearly 300 Board of Trade units; which is far too much.

Whereas if the unit of permeance is fixed high, and the gauss kept small, then the energy corresponding to a gauss-weber may be moderate. Thus with 10^8 c.g.s. as weber, and an ampere-turn as gauss, their product is only $\frac{10^9}{4\pi}$ ergs, or $\frac{100}{4\pi}$ or about 8 joules; which will be useful in energy considerations connected with the heating of transformers.

I therefore propose, in order to retain the ampere-turn as unit of gaussage, that the permeance of a cylinder of material of length l and area A be reckoned as $\frac{\mu\mathrm{A}}{l}$ multiplied by $4\pi \times 10^7$, if dimensions of the cylinder are measured in centimetres; μ being its ordinarily tabulated value with air = 1. If dimensions are measured in inches, then the permeance of a cylinder will be $\frac{\mu\mathrm{A}}{l}$ multiplied by $\frac{4\pi}{2{\cdot}54} \times 10^7$, that is by about $\frac{1}{2}$ 10^8.

The unit of permeance thus suggested is immensely big, and it requires a name of which easy sub-multiples could be formed.

A slab of iron 1 centimetre thick, and with its $\mu = 2500$, would need an area of 5 square metres in order to have unit permeance; but a micro-unit would be possessed by an air-gap a millimetre thick and less than a decimetre square.

PROPOSED RESOLUTIONS.

(1) That the unnecessary prefix "micro" be dropped before the word farad, and that the farad be defined afresh as 10^{-15} c.g.s. electromagnetic units of capacity.

(2) That the name "mo" for the unit of conductance or the ampere per volt, be recognized and adopted. (Every *mo* in a cable enables it to carry an ampere with a drop of 1 volt.)

(3) That the ampere-hour be recognized as a convenient practical unit of electrical quantity.

(4) That the volt-ampere-hour be recognized as a convenient

practical unit of electrical energy, and be called the watt. (It equals 2640 foot-pounds, or a trifle over a foot-ton.)

(5) That the present Board of Trade unit be called a kilowatt.

(6) That the ordinary unit of power be a kilowatt per hour [It equals about 4/3rds of a horse-power, more accurately $\frac{1000}{746}$ HP.]

(7) That it is convenient to retain the name joule in its present sense of a volt-coulomb, or ten million ergs, for use in the science of heat; since heat-capacities are conveniently expressed in joules per degree; and it will be handy to remember that a volt-ampere generates one joule of heat per second.

(8) That the name coulomb be affixed to the electrostatic unit of quantity [for academic purposes].

(9) That a name be given to unit magnetic flux or total induction, and that the name weber is suitable.

(10) That the most convenient size for the weber is 10^8 c.g.s. units or "lines" (since the rate of change of this through a circuit is equal to the induced voltage).

(11) That a name be given to unit magnetic potential or magnetomotive force, and that the name gauss is suitable.

(12) That the handiest size for the gauss is one ampere-turn.

(13) That a name be given to the ratio of the weber to the gauss, or unit of permeance, or self-induction per turn of wire. [If the above resolutions were adopted, this unit would be $4\pi \times 10^7$ c.g.s. units, or $\frac{1}{8}$ secohm per turn.]

(14) That intensities of field be expressed in gausses per unit length, and densities of induction in webers per unit area (leaving the length or area unit open for practical convenience to arrange).

No doubt many of these recommendations have been made before. Mr. Preece has often urged the change of farad, so that I hope there will be no difficulty about that.

I find that my magnetic suggestions are very similar to those suggested by Prof. Perry in his modified letter to the Committee as published in the *Electrician*, vol. xxvii. p. 355 [July 31, 1891], and received there with approving editorial comments. The accordance between our suggestions is satisfactory, and makes it likely that they are such as engineers may be satisfied with and be willing to adopt. I need hardly say that I lay no stress upon the particular *names* here proposed. In choosing them I have been influenced by such trivial considerations as the selection of a monosyllable to correspond with volt, and a dissyllable to correspond with ampere or coulomb.

[With regard to Prof. Perry's footnote concerning college instruction and use of c.g.s. units, I suppose systems of teaching differ, but a senior student *ought* to be taught to deal with concrete quantities in so familiar a manner that no possible admixture of units can be any puzzle to him, nor involve anything worse than a little tiresome arithmetic.]

MECHANICAL UNITS.

There are several quantities in dynamics beside the joule and the watt for which brief names would be advantageous. I do not propose to discuss these fully now, but the present opportunity might be utilized by agreeing to at least one unit, that of pressure, viz., the "atmosphere"; which might be defined as 10^6 c.g.s., or dynes per square centimetre, and stated to be equal to the pressure of a column of mercury 75 centimetres high at a specified temperature. The inconvenient pressure, 76 centims., might be spoken of as a Regnault atmosphere. I believe that a smaller unit of pressure, for instance, the micro-atmosphere or "barad," might also be usefully named. These pressure units will be useful for expressing energies per unit volume also, and the "barad," or whatever other name is decided on for the erg per cubic centimetre, is of reasonable magnitude for many purposes.

OLIVER J. LODGE.

THE INSTITUTION OF MECHANICAL ENGINEERS.

THE annual summer meeting of the Institution of Mechanical Engineers, held last week at Portsmouth, was a successful gathering in regard to numbers present and the attendance at the excursions; but the business part of the meeting, which consists of the sittings at which papers are read, was of a rather tame character. The following is a list of the papers on the agenda:—

On Shipbuilding in Portsmouth Dockyard, by Mr. William H. White, C.B., F.R.S., Director of Naval Construction and Assistant Controller of the Navy.

On the Applications of Electricity in the Royal Dockyards and Navy, by Mr. Henry E. Deadman, Chief Constructor, Portsmouth.

Description of the Lifting and Hauling Appliances in Portsmouth Dockyard, by Mr. John T. Corner, R.N., Chief Engineer, Portsmouth.

Description of the New Royal Pier at Southampton, by James Lemon, J.P., Mayor of Southampton.

Description of the Portsmouth Sewage Outfall Works, by Sir Frederick Bramwell, Bart., D.C.L., LL.D., F.R.S., Past-President.

Description of the New Floating Bridge between Portsmouth and Gosport, by Mr. H. Graham Harris, of London.

Description of the Southampton Sewage Precipitation Works and Refuse Destructor, by Mr. William B. G. Bennett, Borough Engineer and Surveyor.

Description of the Experimental Apparatus and Shaping Machine for Ship Models at the Admiralty Experiment Works, Haslar, by Mr. R. Edmund Froude, of Haslar.

Description of the Pumping Engines and Water Softening Machinery at the Southampton Water Works, by Mr. William Matthews, Waterworks Engineer.

Mr. Matthews' paper was adjourned, and that by Mr. Froude was not read, as time ran short. This was much to be regretted, as the Haslar experimental works are one of the most interesting of all our establishments set apart for scientific investigation. It is to be hoped, now Mr. Froude has broken the ice, that he will contribute a fairly complete descriptive paper to the Institution of Naval Architects, where he would naturally find a more appreciative audience than amongst the members of a society devoted more exclusively to mechanical engineering. Although there was not time for the reading of the paper, Mr. Froude very good-naturedly stopped and explained to some of those present the working of the apparatus which he had brought for the purpose of exhibition, together with the large wall diagrams that had been prepared expressly for illustrating the paper.

On the members assembling in the Town Hall on July 26, Dr. Anderson, the President, occupied the chair, and the usual formal business having been disposed of, Mr. White's paper was read. This was chiefly of a historical character, the author going back to the year 1212, when the sheriff of the county of Southampton was ordered to enclose the King's Dock by a strong wall, and to provide suitable storehouses. A dockyard, properly so called, was not, however, founded until the reign of Henry VIII., so it was second in point of antiquity to Woolwich Dockyard. The latter was closed in 1869, "so that Portsmouth Yard is now," Mr. White says, "the oldest as well as the most important in existence." We do not know whether Mr. White means by this that it is the oldest in existence in Great Britain, or in the whole world. In 1540 the total area was 8 acres. Until nearly the end of last century there was no basin in which ships could lie while completing or repairing, and the dock accommodation was poor, but about that time a basin of 2½ acres and six dry docks were constructed. At that time the yard area was 90 acres. In 1843-50 a steam factory was added, and another basin of 7 acres, besides four docks; the total area of the dockyard being 115 acres. The effect of steam on the navy is well illustrated by the extensions that took place about 1864, when the area of the Dockyard was more than doubled. A fitting-out basin of 14 acres, a rigging basin of the same size, and a repairing basin of 22 acres, were made. There is also a tidal basin of 10 acres. The extent of Portsmouth Dockyard is now nearly 300 acres.

Mr. Deadman's paper was also largely of an historical nature, giving many interesting details of the introduction of electricity into the navy. Among the most notable features in the application of electricity to naval purposes are the temporary installations used for interior lighting during the building and finishing of the vessel. The estimated cost of electric lighting during the period of building the *Royal Arthur* was £1200. This would be about the same sum as would be required were candles used, but naturally electricity affords a far superior light, and it is to its use that is due much of the quickness with which the

Royal Sovereign was finished. There was nothing very startling in Mr. Deadman's paper, which was none the less a useful record of facts. During the discussion, however, Mr. Crompton sounded a very stirring note. He roundly told the whole body of important dockyard officials and Admiralty officers present, including even the Director of Naval Construction, that they were altogether behind the age in the matter of electricity, that the French and German navies were far ahead of them, to say nothing of other powers, and that generally the English Government was the most benighted and non-progressive Government in all the world, so far as the matter of electricity was concerned; for they paid twice as much as they ought to do for an article that was not half as good as it should be. That was the purport of Mr. Crompton's speech, if not the exact words he used, and one cannot but acknowledge that he did not speak altogether without a text. It is hard to fully account for the want of enterprise in the Royal Navy, but there is one point to which we might draw attention. The paper read at the meeting was by a naval constructor, and electricity is, we understand, within the Constructor's department. Now electrical engineering is essentially an engineering question, and its consideration requires engineering knowledge and ability of a very high order. In the early days nothing kept electric lighting back more than the bad engineering that was associated with it; and thus it will always be so long as engineers are not employed in carrying out the plans which are founded on the researches of those more highly scientific investigators, upon whose experiments and deductions the practical applications are founded.

The next paper read was Mr. Corner's contribution, in which he described the lighting and hauling apparatus used at Portsmouth. These may be divided into the hydraulic installation, the compressed-air appliances, and the ordinary steam cranes. There are in the dockyard ninety-six boilers, which burn about 10,000 tons of coal per annum, but what proportion of this is used for lifting and hauling we do not know. In the hydraulic department there are nearly two miles of pressure pipes varying from 1½″ to 4″ in diameter. There are also some independent installations, as well as the coaling arrangements for the fleet at coaling point. There are here ten 30 cwt. cranes, and three 10 ton tips, with necessary capstan weigh-bridges. The more modern lifting and hauling appliances are by compressed air, the air being compressed to 60 lbs. With this pressure there is little or no trouble with frost, only a little forming at the exhaust in very damp weather, and altogether the pneumatic system seems to be preferred to the hydraulic. It must be remembered that the power required is variable, and this of course brings the advantage of the pneumatic system, in the matter of working expansively, to the fore. We understood Mr. Corner to say, during the discussion, that when the hydraulic motors and the air-engines were both worked at their full power the water system was the most economical, but working linked up, under the prevailing conditions, the air system was the best. The condensation of steam in the pipes is the objection to the steam motor when situated at some distance from the boiler, otherwise steam would be the best vehicle. The other papers read do not call for any special notice at our hands, their titles giving a sufficient indication of their scope, and there being no features of especial novelty in the matters they described.

A number of excursions had been arranged, and were carried out in a very satisfactory manner. On the first day, Tuesday, the 26th ult., the members visited the Dockyard, and were welcomed by the Admiral Superintendent in person. On Wednesday the Portsmouth Sewage Works were visited, and a trip was made to the Clarence Victualling Yard at Gosport. On Thursday a trip was made to Southampton, where the Docks were inspected, and a visit was paid to the Union Steamship Company's new engineering shops. There was an alternative visit to the Ordnance Survey Office. In the afternoon a visit was paid to the London and South Western Railway Company's new carriage and wagon shops at Eastleigh. Friday was devoted wholly to frivolity, the only item on the programme being a steamer trip round the Isle of Wight. On Saturday a good many of the members went to Brighton to visit the locomotive works of the London, Brighton and South Coast Railway. Largely owing to the exceptionally fine weather the meeting was a great success, and, for pleasantness, may rank with the Dublin meeting of three or four years back.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—The fifth summer meeting of Oxford University students commenced on July 29, and will continue till August 27. The general outline of the programme has already been noticed in these columns, but we may notice here that the popularity which has attended these gatherings shows no signs of diminishing. It was announced by the Provost of Queen's College, who presided at the inaugural lecture given by Mr. John Addington Symonds, that upwards of 1250 students had come to attend the lectures it was proposed to deliver. In welcoming the students to the meeting, Dr. Magrath remarked that last winter 60,000 students (including 10,000 artisans) regularly attended the extension lectures of the various universities engaged in the work. There had been 312 courses of Oxford lectures. He also commended the co-operative societies of the North, and particularly the Co-operative Union, and mentioned the individual liberality of Mr. Dixon Galpin, who had founded scholarships for students from Dorset to attend this summer meeting. The munificence of Mr. Galpin had been supplemented by the Dorset County Council. A University Extension College had been recently established at Reading, under the presidency of Mr. MacKinder, an example which he hoped would be followed at other centres.

On Monday a conference was held in the Union Debating-room, under the presidency of Mr. J. G. Talbot, M.P., to consider the relations between the County Councils and the University extension movement. The president invited the lecturers under various County Councils to express their opinion as to the advantages, prospects, and difficulties which they had met or encountered in the course of their peripatetic teaching. His own opinion was that one very successful result of these lectures would be the amalgamation of the classes and the masses, and he noticed that one of the candidates to whom a County Council had awarded a scholarship was in the position of an agricultural labourer.

Mr. Hall, who had been a University Lecturer under the Surrey County Council, cautioned the meeting against entertaining any exaggerated views of the actual information that he had been able to convey to the agricultural labourers. He himself was satisfied if he could awaken a desire for knowledge in the rural mind and convince the extremely conservative agriculturist that he had something to learn.

Mr. Sells, of the Yorkshire College, Leeds, described the activity of that portion of the Victoria University, and believed that in the North they were in advance of the Oxford movement in meeting the actual and practical wants of the labouring section of the community. Coal-mining was taken up by them with eagerness, and the agricultural lecturers carried about with them the actual implements of husbandry in order to bring the matter practically before their audience. The discussion was continued by Mr. Sadler, secretary to the Delegacy, who said that alliances had been entered into with twelve large counties in the past year, and they should be proud of the achievement. In his opinion they ought to give a stimulus to learning to the masses, and for this reason they ought also to combine with the elementary teachers. Help should also be given to individuals, and it was necessary to secure the services of good men, by enabling the scheme to compete with other professions in the matter of the remuneration offered.

Mr. MacKinder (University Extension Lecturer) and Dr. Magrath agreed in deprecating any fixed cut and dried plan for the whole country, but thought that the scheme should be varied to meet the different circumstances of the various County Councils. At the same time, each County Council should have a definite policy.

SCIENTIFIC SERIALS.

THE *Quarterly Journal of Microscopical Science* for March 1892, contains:—On a new branchiate Oligochæte (*Branchiura sowerbyi*), by Frank E. Beddard, M.A. (plate xix.). This annelid, found in mud from the "*Victoria regia* tank" in the Royal Botanical Gardens, Regent's Park, London, is remarkable for the unusual contractility of its body, which suggested a leech or flat worm rather than a Chætopod. It consists of about 120 segments. When magnified the orange-coloured digestive tract traversed by the bright blood vessels is seen, and at the posterior end of the body there is a series of delicate dorsal and ventral processes; these latter are segmentally arranged, developed in pairs upon the last sixty segments or so of the body. There is no connection between the setæ and these processes, as in Bourne's Chætobranchus, also found in the same tank. This worm is referred to the Tubificidæ, without having any certain affinities to any of the known genera.—On the formation of the germ-layers in *Crangon vulgaris*, by W. F. R. Weldon, M.A. (plates xx. to xxii.). The author's conception of the early development differs widely from that of Kingsley. —On the pigment cells of the retina, by I. S. Boden and F. C. Sprawson. The retinal pigment cells are not, as usually represented, invariably hexagonal; in specimens taken from the eyes of sheep, ox, rabbit, kitten, pig, hen, and frog, while hexagonal cells were the most numerous, heptagonal cells were frequently found and scattered at intervals. Cells with four, five, eight, nine, ten, and eleven sides were found.—Observations upon the development of the segmentation cavity, the archenteron, the germinal layers, and the amnion in mammals, by Dr. Arthur Robinson (Plates xxiii. to xxvii.). There is a general description of the development of the ova of the rat and mouse up to the period of the completion of the blastodermic vesicle, and a comparison with the results obtained by Fraser, Duval, and Selenka: there is a description of the formation of the mesoblast and of the chorda dorsalis, followed by a comparison of the ova of the rat and mouse with the ova of other mammals and the lower vertebrates and by a description of the formation of the amnion and a discussion of the relation of amnion formation to "inversion," and by a description of the formation of the cœlom.

June.—Contains:—On the primitive segmentation of the vertebrate brain, by Bertram H. Waters, B.A. (Plate xxviii.); concludes that the fore-brain is composed of at least two well-marked neuromeres, possibly of three; that the mid-brain consists of two neuromeres, from which there is every reason to think that the third and fourth nerves take their origin, and hence these deserve to be recognized as segmental structures; and that the hind brain consists of six neuromeres. On the oscula and anatomy of *Leucosolenia clathrus*, O.S., by E. A. Minchin, B.A. (Plate xxix.). In this sponge, in the fresh and healthy condition, not only are there oscula, "but in the full-sized specimens larger oscula than in any other Leucosolenia known to me, whether from pictures or in the flesh." These oscula are provided with a sphincter, and can be so tightly closed as to escape notice. Hæckel's four varieties of the sponge are only different states of contraction.—Researches into the embryology of the Oligochæta, No. 1: on certain points in the development of *Acanthodrilus multiporus*, by Frank E. Beddard, M.A. (Plates xxx. and xxxi.).—On the Innervation of the Cerata of some Nudibranchiata, by Dr. W. A. Herdman and J. A. Clutt (Plates xxxii. to xxxiv.). If the cerata of Nudibranchs cannot all be said to be true epipodia innervated by the pedals, it would seem equally impossible to regard them in all cases as pallial outgrowths supplied by the pleural ganglia. It is possible that they may have been epipodial in origin, although there be now, in some, a connection with pleural nerves.—Notes on Elasmobranch development, by Adam Sedgwick, M.A. (Plate xxxv.). On the paired nephridia of Prosobranchs, the homologies of the only remaining nephridium of most Prosobranchs, and the relations of the nephridia to the gonad and the genital duct, by Dr. R. v. Erlanger (Plates xxxvi. and xxxvii.).

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 16.—"The Physiological Action of the Nitrites of the Paraffin Series considered in connection with their Chemical Constitution. Part II. Action of the Nitrites on Muscular Tissue and Discussion of Results." By J. Theodore Cash, M.D., F.R.S., Professor of Materia Medica in the University of Aberdeen, and Wyndham R. Dunstan, M.A., Professor of Chemistry to the Pharmaceutical Society of Great Britain.

Continuing the examination of the physiological action of various pure organic nitrites of the paraffin series (Part I.; Roy. Soc. Proc., 1891), the authors have studied their effect on striated muscular tissue. When the vapours of these nitrites come into contact with the muscle a paralysant effect is observed. All the experiments were made with the triceps and gastrocnemius of *Rana temporaria*. The muscle was contained in a specially constructed air-tight chamber. A very extensive series of experiments was necessary in order to obtain reliable contrasts. The amounts of the nitrites employed varied between $\frac{1}{30}$ and $\frac{1}{200}$ c.c.

Several series of concordant results have thus been obtained which lead to two different orders of activity, viz. (1) with reference to the extent to which equal quantities of nitrites shorten the resting muscle, and (2) with reference to the rapidity with which the shortening is produced. The order of activity of the nitrites as regards the extent of the shortening they induce is as follows:—(i.) Iso-butyl, (ii.) tertiary amyl, (iii.) secondary butyl, (iv.) secondary propyl, (v.) propyl, (vi.) tertiary butyl, (vii.) butyl, (viii.) α-amyl, (ix.) β-amyl, (x.) ethyl, (xi.) methyl. The order representing the speed with which shortening occurs is (i.) methyl, (ii.) ethyl, (iii.) secondary propyl, (iv.) tertiary amyl, (v.) primary propyl, (vi.) tertiary butyl, (vii.) secondary butyl, (viii.) α-amyl, (ix.) β-amyl, (x.) primary butyl, (xi.) iso-butyl.

The effect of these nutrites in interfering with the active contraction of a stimulated muscle has also been studied, and it has been ascertained that very minute doses, insufficient to cause passive contraction, interfere in a marked degree with the active contraction, and cause the muscle to fail in responding to stimulation, whilst the companion muscle, contained in a closed chamber free from nitrite vapour, still responded to stimulation.

The remainder of the paper is devoted to a discussion of the connection between the various phases of physiological action and the chemical constitution of the nitrites which gave rise to them. The principal conclusions which have been arrived at are briefly as follows:—The physiological action of these nitrites is not solely, and in some cases not even mainly, dependent on the amount of nitroxyl (NO_2) they contain.

In respect of all phases of physiological activity, the secondary and tertiary nitrites are more powerful than the corresponding primary compounds. This is to be chiefly attributed not to the direct physiological action of the secondary and tertiary groups, but to the great facility with which these compounds suffer decomposition mainly into the alcohol and nitrous acid. In respect of the acceleration of the pulse, the power of the nitrites is directly as their molecular weight, and inversely as the quantity of nitroxyl they contain. They, therefore, fall into an order of physiological activity which is identical with that in which they stand in the homologous series. This same relationship holds, though less uniformly, in their power of reducing blood-pressure, and of inducing muscular contraction.

This order appears to be the result not so much of the direct physiological influence of the substituted methyl groups as of the increased chemical instability which their presence confers on the higher members of the series. In respect of the duration of subnormal pressure, as well as of the rapidity with which muscular contraction ensues, the activity of the nitrites is expressed by an order which is for the most part the reverse of that representing their power in accelerating the pulse, reducing blood-pressure, and contracting muscular fibre, this order being in general contrary to that of the homologous series. In these respects the more volatile nitrites of low molecular weight which contain relatively more nitroxyl are the most active. It appears probable that these simpler nitrites more readily attach themselves to certain constituents of blood and muscle, and thus act more quickly than the higher compounds, whilst their greater stability causes their effects, *i.e.*, reduction of blood-pressure, &c., to endure for a greater length of time than that of the higher and more easily decomposed bodies.

A large proportion of an organic nitrite is changed into nitrate in its passage through the organism, and is excreted as an alkali nitrate in the urine.

The results which have been gained by this research have an important bearing on the therapeutic employment of the nitrites. It is proposed elsewhere to consider what the outcome of this investigation is for practical medicine.

PARIS.

Academy of Sciences, July 25.—M. d'Abbadie in the chair. —Some new observations on the employment of the calorimetric shell, by M. Berthelot. Different bodies must be treated differently, according as they are fixed, volatile, or gaseous. For fixed compounds, solid or liquid, the ratio between the weight of the combustible and the weight of oxygen ought to be such that the gas which remains after combustion contains at least 60 per cent. of free oxygen; otherwise some half-burnt gases will remain in the vessel, notably carbonic oxide. Excess of oxygen, especially if under a pressure of 25 atmospheres, ensures that the temperature of the centre of combustion should remain as high as possible. In the case of gases the oxygen should only be in very slight excess, and should be introduced by tenths of an atmosphere, until the most favourable pressure is reached. Volatile bodies should, if possible, be burnt in the liquid state.—Study of boron trisulphide, by M. Henri Moissan. Five new methods of obtaining this body are described: by the action of fused sulphur on boron iodide; by burning boron in sulphur vapour at 610°; by the action of hydrogen sulphide on pure boron; by the action of carbon bisulphide on boron; and by the action of the sulphides of arsenic, antimony, and tin upon boron. The substance thus obtained shows several remarkable properties.—Researches on the chemical constitution of the peptones, by M. P. Schutzenberger.—On two ruminants of the Neolithic epoch of Algeria, by M. A. Pomel.—The two candidates selected for the Directorship of the Paris Observatory were M. Tisserand and M. Loewy.—*Résumé* of solar observations made at the Royal Observatory of the Roman College during the second quarter of 1892. A letter from M. P. Tacchini to the President. The spots, faculæ, and prominences observed show a considerable increase since last quarter.—Sun observations made at the Lyons Observatory (Brunner equatorial) during the first half of 1892, by M. Em. Marchand. 125 groups of sun-spots have been counted, as against 101 in the previous half-year. The southern hemisphere, which used to contain less spots, has lately shown nearly as many as the northern. The latitude of the groups continues to diminish.—New results with regard to hydrogen, obtained by the spectroscopic study of the sun. Similarity with the new star in the Charioteer, by M. Deslandres. In addition to the nine ultra-violet lines of hydrogen already known, five more have been photographed in the spectrum of a very brilliant prominence, extending up to the oscillation frequency 271,700. They correspond very closely with the frequencies calculated from Balmer's harmonic series. The interest of the discovery is augmented by the circumstance that the spectrum obtained shows a great similarity with that of the new star in the Charioteer.—On the velocity of propagation of the electromagnetic undulations in insulating media, and on Maxwell's relation, by M. R. Blondlot. Given an oscillator, the wave-length which it is susceptible of emitting remains the same, whatever may be the insulating medium in which the experiment is made.—On the heat of formation of permolybdic acid and the permolybdates, by M. E. Péchard.—On crystallized phosphide of mercury, by M. Granger.—On the mineralizing action of ammonium sulphate, by M. T. Klobb.—Micrographic analysis of the alloys, by M. Georges Guillemin.—On homopyrocatechine, and two derived nitrides of homopyrocatechine, by M. H. Cousin.—On a new class of combinations, the metallic nitrides, and on the properties of nitrogen peroxide, by MM. Paul Sabatier and J. B. Senderens.—The specific heat of the atoms and their mechanical constitution, by M. G. Hinrichs. On monopropyl urea and dissymmetrical dipropyl urea, by M. F. Chancel.—On the composition of fossil bones, and the variation in their percentage of fluorine during the various geological periods, by M. BERLIN.

Physiological Society, July 8.—Prof. Munck, President, in the chair.—Dr. Dessoir spoke on the sense of temperature regarded from the anatomical, psychological, and physiological point of view. He did not believe in the existence of separate senses for heat and cold since he had failed to obtain sensations of heat and cold by either mechanical or electrical stimulation of certain points of the skin. The temperature sense is localized, since portions of the body-surface can be found which are quite insensitive. The above communication was followed by a lengthy discussion.

July 22.—Prof. Munck, President, in the chair.—Prof. Zuntz had long ago observed that strong muscular exertion has a different effect on the alkalinity of the blood of carnivora as compared with herbivora; thus in dogs the power of their blood to absorb carbon dioxide was practically unaltered by exercise, whereas in rabbits it was considerably lessened. This point had recently been reinvestigated in the speaker's laboratory by Dr. Cohnstein, who found that the blood of a dog at hard work on a treadmill showed no alteration of alkalinity. The result was unaffected by diet, since it was the same when the dog was fed with meat alone, or with rice and fat. During very prolonged exertion the blood was finally found to possess an increased alkalinity. Dr. Lilienfeld had recently discovered Prof. Kossel's "histon" in the leucocytes of blood, united to neuclein as "nucleo-histon." Histon prevents the clotting of blood, whereas nuclein promotes the formation of fibrin. These two facts were regarded as explaining the various phenomena connected with blood clotting. Thus the blood is fluid in the blood vessels because nucleo-histon is retained by the leucocytes. On the other hand, when the blood is shed some of the leucocytes or platelets die, whereupon the nucleo-histon escapes into the plasma, is decomposed by the calcium salts there present into nuclein and histon, and the former (nuclein) then causes clotting. These facts also explain the action of calcium salts in promoting clotting. Prof. Zuntz stated that, according to his researches, a taste-sensation, as of something sweet, is very markedly increased when some other stimulus is simultaneously applied to the organ of taste, even when the stimulus is too weak to alone produce any sensation. Thus, for example, a solution of sugar tastes more sweet if it is mixed with some solution of common salt so weak that it excites no saline taste. The same result was obtained by the addition of a solution of quinine, also too weak to itself give rise to any sensation of taste.

THURSDAY, AUGUST 11, 1892.

THE BRITISH ASSOCIATION.

EDINBURGH.

THE Edinburgh meeting has not been remarkable for a large turn-out of members. Probably the greatest number of members are present on the Friday, when practically all have come and none have left. At this high-water mark the number of members, associates, and holders of transferable ladies' tickets, was 2009, and although the tickets sold were increased to 2068 by Wednesday, the total attendance probably never quite reached 2000, which, although greater than last year's meeting at Cardiff, is much less than that twenty-one years ago at Edinburgh. Year by year the number of ladies taking part in the proceedings mounts steadily, and on several occasions the "popular" sections of anthropology and geography, which were frequently crowded, showed a great preponderance. Everything has not gone quite smoothly in spite of the efforts of the local secretaries. Edinburgh society is inelastic in its traditions, and Edinburgh institutions are ruled by rigid laws, which even a meeting of the British Association finds difficulty in relaxing. For the first day or two the reading and writing rooms and other apartments were closed at 5 p.m., as they occupy part of the Advocates' Library, while the reception-room being in Parliament House remained open for the usual time. Unqualified praise can be given to the commissariat arrangements. The main luncheon-room in the Students' Union was deservedly busy from 1 to 3. The handsome building containing these commodious rooms was greatly admired, and the enterprise of the students to whose efforts alone its construction is due, and by whom alone it is managed, was the subject of frequent comment. Passing between the section rooms and the Union members availed themselves of frequent opportunities to inspect the great MacEwen Hall of the University, now approaching completion, the prospective use of which, by the way, was one of the considerations that led the deputation from Edinburgh to defer to that from Cardiff in arranging the order of the Association's visits to the respective towns.

Rarely is it the privilege of the mixed multitude who throng the hall on the opening night of the meeting to listen to so comprehensible and attractive an address as the President delivered on this occasion. Sir Archibald Geikie's lucid exposition was crowned by a characteristically happy speech by Lord Kelvin in moving the vote of thanks. Altogether the first gathering dealt a blow at the belief, still amusingly common, that the true scientific man is a being of terms and formulæ, and that true science is colourless and unsympathetic. The other evening discourses were highly appreciated, and maintained the high character which the Association lectures have made for themselves. Prof. Milnes Marshall played upon his vague title of "Pedigrees" until the scintillations lit up a great part of the theory of evolution; while Prof. Ewing on Magnetic Induction threw a flood of light on what has hitherto been to ordinary minds one of the obscurest recesses of physics. The lecture to the working classes, from which members of the Association are excluded—unless they attend on false pretences—turned out a great success. Mr. Vernon Boys showed and explained his wonderful experiments on photographing bullets and the waves they produce in traversing the air with point and brilliancy. The work in some of the Sections has been of a high order of excellence; in Section A especially very few British physicists were absent, and some of the discussions alone justified the existence of the Association as a means of bringing men together from different working centres. The reading of the various reports in the different Sections in some cases gave rise to suggestions of high value for future work. Unfortunately, in consequence of the illness of the President, the address in the Geological Section was not read till Monday. It was not then quite complete, so its publication is postponed for the present.

Edinburgh, if possible, exceeded its old reputation for hospitality, and meetings of a purely social character were unusually numerous, and the two conversaziones proved thoroughly enjoyable.

Excursions practically took up the whole of Saturday, and an unusually large number took advantage of the opportunity for visiting the many scenes of historical, archæological, geological, and engineering interest which lie around Edinburgh. The range was by no means restricted to the immediate vicinity, the excellent railway arrangements permitting of visits to Glasgow, Dundee, and the land of Scott, with no greater expenditure of time than the carriage parties demanded for visiting the Forth Bridge and Roslin, or the pedestrians for geologizing in the Pentlands and on Arthur's Seat. The weather for the first few days was favourable, being dry and free from excessive heat. But Monday was a most unfortunate sample of Edinburgh's weather at its worst, strong east wind and cold continual showers; even this state of matters failed to empty the section-rooms where papers of popular interest were being read. Afternoon receptions both public and private, were particularly well managed, perhaps the most enjoyable being that given by the Royal Scottish Geographical Society in the spacious halls of the National Portrait Gallery, where the Antiquarian Museum is now worthily housed. A special reception of foreign members was also given by the University in the Library Hall. The number of distinguished foreigners present marked out this meeting from most others of recent years. The Prince of Monaco, who, with the princess, lived on board his new yacht the *Princesse Alice*, was perhaps the greatest attraction, and he succeeded in bringing together one of the largest audiences to listen to his papers in Section E. He also showed his yacht to a select party of members specially interested in marine studies, and took endless trouble in explaining the ingenious original devices for deep-sea research with which she is fitted. Profs. von Helmholz, Wiedemann, von Richthofen, Ostwald, and Goebel worthily represented the science of German Universities, and many of their somewhat less distinguished colleagues were also present. Baron de Guerner, MM. de Margine, Demolins, Bertrand, Manouvrier, Guillaume, and Richard came from France, the Abbé Renard and Profs. Errera and Hulin from Belgium, Drs. Arrhenius and Pettersson from Sweden, Prof. Fritsch and others well known in the scientific world from Austria, while the United States, Holland, Russia, and Switzerland were also represented. The brilliant young physicist, Nikola Tesla, appears in the list as a visitor from America.

A small meeting unfortunately means a small sum available for grants to scientific workers, and on account of the large sums asked for by the various Sections, the work of the Committee of Recommendations was no sinecure.

Next year's meeting will be held at Nottingham, and that for 1894 at Oxford.

The list of awards finally arrived at was as follows:—

Investigation of the Eruptive Deposits of Pentland Hills	£10
Isomeric Naphthalene Derivatives	20
Index of Plants, &c.	20
Climatology, &c., of Africa	50
Place Names in Scotland	10
Electrical Measurements	25
Observations on Ben Nevis	150
Falmouth Observatory	25
Photography of Meteorological Phenomena	10
Solar Radiation	10
Spectra of Elements	10
Analyses of Iron and Steel	20
Action of Light on Dyed Colours	5
Erratic Blocks of England, Wales, and Ireland	10
Fossil Phyllopoda	5
Geological Intervals	10
Underground Waters...	5
High-level Shell-bearing Deposits	20
Zoological Station at Naples	100
Plymouth Biological Station	30
Sandwich Islands	100
West Indies	50
Irish Sea Exploration	30
Oxygen in Asphyxia	20
Exploration of the Karakorum Mountains	50
Methods of Economic Training	5
Anthropometric Tabulations	5
Exploration of Assam	25
North-West Tribes of Canada	100
Natives of India	10
Corresponding Societies Committee	30
Total ...	£970

SECTION D.

BIOLOGY.

OPENING ADDRESS BY PROF. WILLIAM RUTHERFORD, M.D., F.R.S., PRESIDENT OF THE SECTION.

AT the meeting of this Association held at Birmingham in 1886 I had the honour of delivering a lecture on the Sense of Hearing, in which I criticized the current theory of tone-sensation, and I propose on this occasion to discuss the current theories regarding our sense of colour.

I may premise that our conceptions of the outer world are entirely founded on the experience gathered from our sensory impressions. Through our organs of sensation, mechanical, chemical, and radiant energies impress our consciousness. The manner in which the physical agents stimulate the peripheral sense-organs, the nature of the movement transmitted through our nerves to the centres for sensation in the brain, the manner in which different qualities of sensation are there produced—all these are problems of endless interest to the physiologist and psychologist.

Every psychologist has acknowledged the profound significance of Johannes Müller's law of the specific energies—or, as we should rather say, the specific activities of the sense-organs. To those unfamiliar with it, I may explain it by saying, that if a motor nerve be stimulated, the obvious result is muscular movement; it matters not by what form of energy the nerve is stimulated—it may be by electricity or heat, by a mechanical pinch or a chemical stimulus, the specific result is muscular contraction. In like manner, when the nerve of sight is stimulated—it may be by light falling on the retina, or by electricity, or mechanical pressure, or by cutting the nerve—the invariable result is a luminous sensation, because the impression is transmitted to cells in the centre for vision in the brain, whose specific function is to produce a sense of light.

The same principle applies to the other sensory centres; when thrown into activity, they each produce a special kind of sensation. The sun's rays falling on the skin induce a sense of heat, but falling on the eye, they induce a sense of sight. In both cases the physical agent is the same; the difference of result arises from specific differences of function in the brain centres concerned in thermal and visual sense. We have no conception how it is that different kinds of sensation arise from molecular movements in the different groups of sensory cells; we are as ignorant of that as we are of the nature of consciousness itself.

The subject I propose to discuss on this occasion is not the cause of the different *kinds* of sensation proper to the different sense-organs, but the causes of some *qualities* of sensation producible through one and the same sense-organ.

The theory of tone-sensation proposed by Helmholz is, that the ear contains an elaborate series of nerve terminals capable of responding to tones varying in pitch from 16 vibrations to upwards of 40,000 vibrations per second, and that at least one different fibre in the auditory nerve, and at least one different cell in the centre for hearing, is affected by every tone of perceptibly different pitch. Although the physical difference between high and low tones is simply a difference in frequency of the sound waves, that is not supposed by Helmholz to be the cause of the different sensations of pitch. According to his theory, the function of frequency of vibration is simply to excite by sympathy different nerve terminals in the ear. The molecular movement in all the nerve fibres is supposed to be identical, and the different sensations of pitch are ascribed to a highly specialized condition of cells in the hearing centre, whereby each cell, so to speak, produces the sensation of a tone of definite pitch, which in no way depends on the frequency of incoming nerve impulses, but simply on the specific activity of the cell concerned.

In my lecture on the Sense of Hearing I pointed out in detail the great anatomical difficulties attending the theory in question. I endeavoured to show the physical defect of a theory which does not suppose that our sensations of harmony and discord must immediately depend upon the numerical ratios of nerve vibrations transmitted from the ear to the central organ, and I offered a new theory of hearing based upon the analogy of the telephone. According to that theory, there is probably no analysis of sound in the ear; the air-cells at the peripheral ends of the auditory nerve are probably affected by every audible sound of whatever pitch. When stimulated by sound they probably produce nerve vibration, simple or compound, whose frequency, amplitude, and wave-form correspond to those of the sound received. The nerve vibrations arriving in the cells of the auditory centre probably induce simple sensations of tones of different pitch, or compound sensations of harmonies or discords strictly dependent on the relative frequencies of the nerve vibrations coming in through the nerve.

I cannot now recapitulate the evidence derived from anatomical, experimental, and pathological observations that give support to my theory of hearing, but I may briefly say that it is opposed to the theory of specific activities, in so far as it has been applied to explain the different qualities of sound sensation. It is, however, in strict accord with the fundamental proposition stated by Fechner[1] in his great work on Psychophysics in these words: "The first, the fundamental hypothesis is, that the activities in our nervous system on which the sensations of light and sound functionally depend are, not less than the light and sound themselves, to be regarded as dependent on vibratory movements." It is evident that, if we could only comprehend the nature of the molecular movement in the nerve that links the vibration of the physical agent to that in the sensory cell, we could advance towards a true theory of the physiological basis of different qualities of sensation in the different sense-organs. As yet no definite answer can be given to the question, what sort of molecular movement constitutes a nerve impulse, but in recent years our knowledge of the subject has been extended in a direction that opens up a vista of new possibilities.

A nerve impulse travels at a rate not much more than 100 feet per second—an extremely slow speed compared with that of electricity in a wire. It has been thought to be of the nature of a chemical change sweeping along the nerve, but that hypothesis is opposed by the fact that the most delicate thermopile shows no production of heat, even when an impulse is caused to sweep repeatedly along the same nerve. Again, it is far easier to fatigue a muscle than a nerve. A living frog's nerve removed from the animal, and therefore deprived of all nutrition, can retain its excitability for nearly an hour, although subjected all the while to thirty or forty stimulations per second. An excised muscle, when similarly stimulated, is exhausted far sooner, because the mechanical energy entirely springs from chemical change in the muscular substance, and therefore the muscle is more easily fatigued than the nerve. The molecular motion in an excited nerve produces a momentary electric current; but that result is not peculiar to nerve. The same occurs in muscle when stimulated. Possibly the molecular movement is of the nature of a mechanical vibration; at all events, we know now that a nerve can transmit hundreds, even thousands of impulses, or let us simply say vibrations, per second. The fact is so important and significant in relation to the physiology of the sense organs, that I show you an experiment to render it more intelligible. A frog's muscle has been hooked to a light lever to record its movement on a smoked cylinder. The nerve of the muscle has been laid on two electrodes connected with the secondary coil of an induction machine. In the primary circuit a vibrating reed has been introduced to serve as a key for making and breaking the circuit, and so stimulating the nerve with periodic induction shocks. If we make the reed long enough to vibrate ten times per second, ten impulses are sent through the nerve to the muscle and ten distinct contractions produced, as shown by the wavy line upon the cylinder. If we shorten the reed so that it will vibrate, say, fifty times per second, the muscle is thrown into a continuous contraction and traces a smooth line on the cylinder; but if we listen to the muscle we can hear a tone having a pitch of fifty vibrations per second, from which we know that fifty nerve impulses are entering the muscle and inducing fifty shocks of chemical discharge in the muscular substance. If we take a reed that vibrates, say, 500 times per second, we hear, on listening to the muscle, a tone having the pitch of 500 vibrations. Observe, that we are not dealing with the transmission of electrical shocks along the nerve, but with the transmission of nerve impulses. By stimulating the nerve with wires of a telephone it has been shown by D'Arsonval that a nerve can transmit upwards of 5000 vibrations per second, and that the wave-forms may be so perfect that the complex electrical waves produced in the telephone by the vowel sounds can be reproduced in the sound of a muscle after having been translated into nerve vibrations and transmitted along a nerve. Such experiments go far in helping us towards a comprehension of the capabilities of nerves in transmitting nerve vibrations of great frequency and complicated wave form; but although they enable us reasonably to suppose that all the fibres of the auditory nerve can transmit nerve vibrations, simple or complex, and with a frequency similar to that of all audible tones, we encounter superlative difficulty in applying such a theory to the sense of sight. In objective sound we have to deal with a comparatively simple wave motion, whose frequency of vibration is not difficult to grasp even at the highest limit of audible sound—about 40,000 vibrations per second. But in objective light the frequency of vibration is so enormous—amounting to hundreds of billions per second—that every one feels the difficulty of forming any conception of the manner in which different frequencies of ether waves induce differences in colour sensation.

---

[1] "Elemente der Psychophysik," 1860 2nd edition, 1889, part ii. p. 282.

But before passing to colour sense, I wish to allude for a moment to the sense of smell. The terminals of the olfactory nerve in the nose are epithelial cells. It has been recently shown by Von Brunn [1] that in man and other mammals the cells have at their free ends very delicate short hairs, resembling those long known in lower vertebrates. These hairs must be the terminal structures affected by substances that induce smell, and are therefore analogous to the hairs on the terminal cells in our organ of hearing. No one ever suggested that the hairs of the auditory cells can analyze sounds by responding to particular vibrations, and I think it quite as improbable that the hairs on any particular olfactory cell respond to the molecular vibrations of any particular substance. If we follow those who have had recourse to the doctrine of specific activities to explain the production of different smells, we must suppose that at least one special epithelial cell and nerve fibre are affected by each different smelling substance. Considering how great is the variety of smells, and that their number increases with the production of new substances, it would be a somewhat serious stretch of imagination to suppose that for each new smell of a substance yet to emerge from the retort of the chemist there is in waiting a special nerve terminal in the nose. It seems to me far simpler to suppose that all the hairs of the olfactory cells are affected by every smelling substance, and that the different qualities of smell result from difference in the frequency and form of the vibrations initiated by the action of the chemical molecules on the olfactory cells and transmitted to the brain. That hypothesis was, I believe, first suggested by Prof. Ramsay,[1] of Bristol, in 1882, and it seems to me the only intelligible theory of smell yet offered. But it must be admitted that a theory of smell, such as that advanced by Ramsay, involves a more subtle conception of the molecular vibrations in nerve fibrils than is required in the case of hearing. It involves the conception that musk, camphor, and similar substances produce their characteristic qualities of smell by setting up nerve vibrations of different frequencies and probably of different complexities. We shall see what bearing this may have on the theory of colour sense, to which I now pass.

No impressions derived from external Nature yield so much calm joy to the mind as our sensation of colour. Pure tones and perfect harmonies produce delightful sensations, but they are outrivalled by the colour effects of a glorious sunset. Without our sense of colour all Nature would appear dressed in bold black and white, or indifferent grey. We would recognize, as now, the beauty of shapely forms, but they would be as the cold engraving contrasted with the brilliant canvas of Titian. The beautiful tints we so readily associate with natural objects are all of them sensations produced in our brain. Paradox though it appear, all Nature is really in darkness. The radiant energy that streams from a sun is but a subtle wave-motion, which produces the common effects of heat on all bodies, dead or living. It does not dispel the darkness of Nature until it falls on a living eye, and produces the sense of light. Objective light is only a wave motion in an ethereal medium; subjective light is a sensation produced by molecular vibration in our nerve apparatus.

The sensory mechanism concerned in sight consists of the retina, the optic nerve, and the centre for visual sensation in the occipital lobe of the brain. In the vertebrate eye the fibres of the optic nerve spread out in the inner part of the retina, and are connected with several layers of ganglionic cells placed external to them. The light has to stream through the fibres and ganglionic layers to reach the visual cells—that is, the nerve terminals placed in the outer part of the retina. They may be regarded as epithelial cells, whose peripheral ends are developed into peculiar rod- and cone-shaped bodies, while their central ends are in physiological continuity with nerve fibrils. Each rod and cone consists of an inner and an outer segment. The outer segment is a pile of exceedingly thin, transparent, doubly refractive discs, colourless in the cone, but coloured pink or purple in the rod. In man, the inner segment of both rod and cone is colourless and transparent. Its outer part appears to be a compact mass of fine fibrils that pass imperceptibly into the homogeneous-looking protoplasm in the shaft of the cell. Owing to the position of the rods and cones, the light first traverses their inner, then their outer segments, and its unabsorbed portion passes on to the adjacent layer of dark-brown pigment cells by which it is absorbed. It is not necessary for me to discuss the possible difference of function between the rods and cones. I may simply say that in the central part of the yellow spot of the retina, where vision is most acute, and from which we derive most of our impressions of form and colour, the only sensory terminals are the cones. A single cone can enable us to obtain a distinct visual impression. If two small pencils of light fall on the same cone the resulting sensory impression is single. To produce a double impression the luminous pencils must fall on at least two cones. That shows how distinct must be the path pursued by the nerve impulse from a visual cell in the yellow spot of the retina to a sensory cell in the brain. The impulses from adjacent terminals must pursue their own discrete paths through the apparent labyrinth of nerve fibrils and ganglion cells in the retina to the fibres of the optic nerve. How these facts bear on the theory of colour sense will presently be apparent. Meantime I pass to the physical agent that stimulates the retina.

When a beam of white light is dispersed by a prism or diffraction grating, the ether-waves are spread out in the order of their frequency of undulation. The undulations of radiant energy extend through a range of many octaves, but those able to stimulate the retina are comprised within a range of rather less than one octave, extending from a frequency of about 395 billions per second at the extreme red to about 757 billions at the extreme violet end of the visible spectrum. The ultra-violet waves in the spectrum of sunlight extend through rather more than half an octave. Although mainly revealed by their chemical effects, they are not altogether invisible: their colour is bluish-grey. The only *optical*—that is, strictly *physical*—difference between the several ether-waves in the visible or invisible spectrum is frequency of undulation, or, otherwise expressed, a difference in wave-length. The *chromatic*—that is the colour-producing—effects of the ether-waves depend on their power of exciting sensations of colour, which vary with their frequency of undulation.

---

[1] Von Brunn, *Archiv für mikroskopische Anatomie*, 1892, Band 39.

[1] Ramsay, NATURE, 1882, vol. xxvi. p. 189.

Although the retina is extremely sensitive to differences in the frequency of ether-waves, it is not equally so for all parts of the spectrum. In the red and blue portions, the frequency varies considerably without producing marked difference of colour effect, but in the region of yellow and green, comparatively slight variations in frequency produce appreciable differences of colour sensation. One striking difference between the effect of ether-waves on the eye and sound waves on the ear is the absence of anything corresponding to the octave of tone sensation. The ether-waves in the ultra-violet, which have twice the frequency of those of the red end of the spectrum, give rise to no sense of redness, but merely that of a bluish-grey. Even within the octave there are no harmonies or discords of colour sense corresponding to those of tone sensation.

Colours are commonly defined by three qualities or constants,—hue, purity, and brightness. Their hue depends upon the chromatic effect of frequency of undulation or wave length. Their purity or saturation depends on freedom from admixture with sensations produced by other colours or by white light. Their brightness or luminosity depends on the degree to which the sensory mechanism is stimulated. The loudness of sound depends on the amount of excitement produced in the auditory mechanism by the amplitude of sound waves; but a sound with small amplitude of undulation may seem loud when the nerve apparatus is unduly sensitive. The brightest colour of the spectrum is orange-yellow, but it does not follow that the amplitude or energy of the ether-waves is greater than in the region of dull red. There is no physical evidence of greater amplitude in the orange-yellow, and its greater luminosity is no doubt purely subjective, and arises from the greater commotion induced in the sensory mechanism.

The theory of colour sense long ago proposed by Sir Isaac Newton[1] is now commonly treated with what seems to me very undeserved neglect. Newton supposed that the rays of light induce vibrations in the retina which are transmitted by its nerve to the sensorium, and there induce different colour sensations according to the length of the incoming vibrations—the longest producing sensations of red and yellow, the shortest blue and violet, those of medium length a sense of green, and a mixture of them all giving a sense of whiteness. At the beginning of this century Thomas Young proposed a theory which seems to have been intended as a modification of that suggested by Newton rather than as a substitute for it. Young supposed that the ether-waves induce vibrations in the retina "whose frequency must depend on the constitution of its substance; but as it is almost impossible to conceive that each sensitive point of the retina contains an infinite number of particles, each capable of vibrating in unison with every possible undulation, it becomes necessary to suppose the number limited to three primary colours, red, yellow, and blue, and that each sensitive filament of the nerve may consist of three portions, one for each principal colour."[2] Soon afterwards he substituted green for yellow, and violet for blue, so that he came to regard red, green, and violet as the three fundamental colour sensations, by mixture of which in varying proportions, all other colours, including white, are produced. Young believed that his suggestion "simplified the theory of colours, and might therefore be adopted with advantage until found inconsistent with any of the phenomena."

Young's trichromic theory of colour sense was adopted by Clerk-Maxwell and Von Helmholz, and underwent important amplification. Helmholz suggested that the three sets of fibres supposed by Young to exist in the optic nerve are connected with three sets of terminals in the retina; that each terminal contains a different visual substance capable of being decomposed by light; that when the substance in the red nerve terminal undergoes chemical change its nerve fibre is stimulated, and the excitement travels to a cell in the brain by whose specific activity the sensation of red arises. In like manner, when the visual substances in the green and violet terminals are decomposed, nerve impulses travel through different fibres to different cells in the vision centre, by whose specific activities the sensations of green and violet arise. With Helmholz there was no question as to difference in quality of sensation depending on difference in frequency of nerve vibration arriving in the sensorium; no such hypothesis was entertained by him either for tone or for colour sensation. With sight, as with hearing, he supposed that the function of frequency of undulation virtually stops at the nerve terminals in the eye and ear, and that the frequency of undulation of the physical agent has no correlative in the quality of motion passing from the receiving terminal to the sensory cell. He believes that the different frequencies of ether-waves simply excite chemical changes in different nerve terminals. He expressly states[1] that the molecular commotion in the nerve fibres for red, green, and violet is identical in kind, and that its different effects depend on the specific activities of the different cells to which it passes in the sensorium. It is evident that Helmholz entirely dismissed the Newtonian theory of the production of different qualities of colour sense, and substituted for it the doctrine of his own great teacher, Johannes Müller.

The theory of Young and Helmholz offers an explanation of so many facts, and has at the same time provoked so much criticism, that I must enter more fully into some of its details. On this theory, the sense of white or grey is supposed to result from a simultaneous and duly balanced stimulation of the red, green, and violet terminals. The red terminals are supposed to be excited chiefly by the longer waves in the region of the red, orange, and yellow, but also by the shorter undulations extending as far as Fraunhofer's line F at the beginning of the blue. In like manner, the green terminals are excited chiefly by the waves of medium length, and to a less extent by the waves extending to C in the red, and by the shorter waves extending to G in the violet. The violet terminals are stimulated most powerfully by the shorter undulations between F and G, but also by the longer ones reaching as far as D in the yellow; therefore, optically homogeneous light from any part of the spectrum, except its extreme ends, does not usually give rise to a pure colour sensation; all three primary sensations are present, and consequently the colour inclines towards white—the more, the stronger the light.

The experimental facts in support of Young's theory are familiar to all who have studied physics. Compound colour sensations may be produced by causing light of different wave lengths to fall simultaneously or in rapid succession on the same part of the retina. The commonest experimental device is to rapidly whirl discs with sectors of different colours, and observe the results of the mixed sensations; or to cause the images of coloured wafers or papers to fall simultaneously on the retina by Lambert's method; or to transmit light through glass of different colours, and cause the different rays to fall on the same surface; or to mix pure homogeneous light from different parts of the spectrum. For obvious reasons, the last method yields the most trustworthy results. We cannot, by any mixture of homogeneous light from different parts of the spectrum, obtain a pure red or green sensation, and according to Helmholz, the same holds true of violet. On the other hand, a mixture of homogeneous rays from the red and green parts produces orange or yellow, according to the proportions employed. A mixture of rays from the green and violet gives rise to intermediate tints of blue, and a mixture of red and violet light produces purple. Therefore, Young regarded red, green, and violet as primary sensations, and orange, yellow, and blue—just as much as purple—he regarded as secondary or compound sensations. Helmholz discovered that to obtain a sense of white or grey it is not necessary to mingle rays from the red, green, and violet portions of the spectrum. He found that he could obtain a white sensation by mixing only *two* optically homogeneous rays from several parts of the right and left halves of the spectrum. The pairs of spectral colours which he found complementary to each other are, red and greenish-blue, orange and cyan-blue, yellow and ultramarine-blue, greenish-yellow and violet; the complement for pure green being found not in any homogeneous light, but in purple—a mixture of red and violet. The complementary colours may be arranged in a circle, with the complementaries in each pair placed opposite one another. Of course, the circle cannot be completed by the colours of the spectrum; purple must be added to fill in the gap between the red and violet. Helmholz found no constant ratios between the wave lengths of homogeneous complementaries; and it is a striking fact that, while a mixture of the green and red, or of the green and violet undulations gives rise to a sensation such as could be produced by rays of intermediate wave length, no such effect follows the mingling of rays from opposite halves of the spectrum. Pure green, with a wave length of 527 millionths of a millimetre, marks the division between the right and left halves. The mixture of blue from the right and yellow from the left side does not produce the intermediate green, but a sensation of white. A mixture of blue or violet and red produces not green, but its complementary—purple. On the trichromic theory, the sense of white produced by the mingling of any of these two colours is simply regarded as the result of a balanced stimulation of the red, green, and violet terminals.

---

[1] Von Helmholz, *Handbuch der physiologischen Optik*, 2nd edition, 1892, p. 350.

But Young's theory is beset with serious difficulties. It implies the existence of three sets of terminals in the retina, and these must all be found in the central part of the yellow spot where cones alone are present. Three sets of cones there would be necessary to respond to the red, green, and violet light, and a colourless pencil of light could not be seen uncoloured, unless it falls on three cones, which we know from astronomical observations is not the case. Therefore, if there are three different terminals, it seems necessary, in the human retina at all events, that they should be found in every single cone in the yellow spot. But I cannot believe it possible that within a single cone there can be three sets of fibrils capable of simultaneous stimulation in different degrees, and of ultimately transmitting impulses through three different fibres to three different cells in the brain. That would imply a greater number of fibres in the optic nerve, than of terminals in the retina, and we know that precisely the reverse is the case. The anatomical difficulty is therefore great, and I am unable to see how it can be surmounted.

The phenomena of colour-blindness also offer great difficulty. In several cases of apoplectic seizure it has happened that the centre for vision on both sides of the brain has been completely or partially paralyzed by the extravasated blood. In such cases the sense of colour may be entirely lost either for a time or permanently, while the sense of light and form remain—although impaired. The loss of colour sense in some cases has been found complete in both eyes; in most of the recorded cases the loss of colour sense was limited to the right or left halves of both eyes; that is, if the lesion affected the vision centre on the right side of the brain, the right halves of both eyes were blind to all colours. That illustrates the fact that a sense of light does not necessarily imply a sense of colour. The colour sense probably involves a more highly refined action of the sensory cell than the mere sense of light and form, and is on that account more liable to be lost when the nutrition of the sensory cell is interfered with. In the normal eye the peripheral zone of the retina is totally blind to colour. If you turn the right eye outwards, close the left, and then move a strip of coloured paper from the left to the right in front of the nose, the image of the paper will first fall on the peripheral zone of the retina, and its form will be seen, though indistinctly, but not its colour. It is difficult to say in that case whether the colour-blindness is due to the state of the retina or to that portion of the vision centre in the brain associated with it. The absence of cones from the peripheral part of the retina has been assigned as the cause, but it is much more probable that the portion of the vision centre associated with the periphery of the retina, being comparatively little used, is less highly developed for form sensation, and not at all for colour sense. It is evident that the production of a sense of white or grey in the absence of all colour sense is not to be explained on the theory that it results from a balanced stimulation of red, green, and violet nerve terminals.

I need scarcely say that colour-blindness has attracted a large share of attention, not only because of its scientific interest, but still more on account of its practical importance in relation to the correct observation of coloured signals. In 1855 the late Prof. George Wilson,[1] of this city, called attention to the growing importance of the subject. Some years ago Prof. Holmgren made an elaborate statistical inquiry regarding it at the instance of the Swedish Government, and lately it has been investigated by a committee of the Royal Society of London, who have quite recently published their report.[1]

Although colour-blindness occasionally results from disease of the brain, retina, or optic nerve, it is usually congenital. Total colour-blindness is extremely rare, but partial colour-blindness is not uncommon. It occurs in about 4 per cent. of males, but in less than 1 per 1000 of females. Its most common form is termed red-green blindness, in which red and green sensations appear to be absent. So far as I can find, the first full and reliable account of the state of vision in red-green blindness is that given in 1859 by Mr. Pole,[2] of London, from an examination of his own case, which appears to be a typical one. The state of his vision is dichromic; his two-colour sensations are yellow and blue. The red, orange, and yellowish-green parts of the spectrum appear to him yellow of different shades. Greenish-blue and violet appear blue, and between the yellow and blue portions of the spectrum, as it appears to him, there is a colourless grey band in the position of the full green of the ordinary spectrum. This neutral band is seen in the spectrum in all cases of dichromic vision. It may appear white or grey according to the intensity of the light, and it apparently results from an equilibrium of the two sensations; no such band is seen in the spectrum by a normal eye. Mr. Pole, in the account of his case given now three and thirty years ago, considered it impossible to explain his dichromatic vision on the commonly received theory that his sense of red is alone defective, and that his sense of yellow is a compound of blue and green. He believed his green quite as defective as his red sensation, and that yellow and blue are quite as much entitled to be considered fundamental sensations as red and green. He suggested that in normal colour vision there are at least four primary sensations—red and green, yellow and blue. Prof. Hering is commonly accredited with the four-colour theory, but it was previously suggested by Pole.[3]

A year after Pole's paper appeared, Clerk-Maxwell[4] published his celebrated paper on the theory of compound colours, to which he appended an account of his observations on a case of what he believed to be red-blindness, but which we now know must have been red-green blindness. The spectrum appeared dichromic, its only colours being yellow and blue. His description of the case does not materially differ from that given by Pole; but Clerk-Maxwell believed in the trichromic theory of normal vision, and that red-green and blue are the three primary sensations; consequently he supposed that the yellow sensation of a red blind person is not pure yellow, but green.

It is evident that much depends on the question, "Is the yellow sensation of a red-green blind person the same as that of normal vision?" For many years it was impossible to give a definite answer to that question, but the answer can now be given, as we shall immediately see. Colour-blindness is frequently hereditary, and two or three cases are known in which the defective colour sense was limited to one eye, while in the other eye colour vision was normal. In such a case observed by Prof. Hippel, of Giessen, there was red-green blindness in one eye. Holmgren, who examined Hippel's case, has published an account of it.[5] With one eye all the colours of the spectrum were seen, but to the other eye the spectrum had only two colours with a narrow grey band between them at the junction of the blue and yellow. The yellow seen by the eye with the red-green defect had a greenish tinge like that of a lemon, but in other respects the observations confirmed Pole's account of his own case.

Hippel's case seems to me important for another reason. By some it is believed that congenital colour defect is due to the brain. If there had been defective colour sense on one side of the brain, it would not have implicated the whole of one eye, but the half of each eye. Its limitation to one eye, therefore, seems to me to suggest that the fault was in the eye rather than in the brain.

Another interesting fact in this relation is that in every normal eye, just behind the peripheral zone of total colour-blindness, to which I have already referred, there is a narrow zone in which red and green sensations are entirely wanting, while blue and yellow sensations are normal. Possibly the red-green defect is due to an imperfectly developed colour sense in the portion of the vision centre connected with that zone of the retina, but Hippel's case seems to me to show that such defect might be on the retina.

It has probably already struck you that red-green blindness is really blindness to red, green, and violet, that Young's three primary sensations appear to be absent, and the two remaining colours are those which he regarded as secondary compounds of his primaries.

That, however, is not all that is revealed by colour-blindness. There is at least another well-known though rare form in which a sense of yellow, blue, and violet is absent, and the only colour sensations present are red and green. The defect is sometimes termed violet blindness, but the term is somewhat misleading. It is much more in accordance with the fact to term it yellow-blue blindness; indeed, we would define it precisely by terming it yellow-blue-violet blindness. Holmgren[1] has recorded a unilateral case of that defect analogous to Hippel's case of unilateral red-green defect; we therefore know definitely how the spectrum appears to such a person. In the case referred to all the colours of the spectrum were seen with the normal eye, but to the other eye the spectrum had only two colours, red and green. The red colour extended over the whole left side of the spectrum to a neutral band in the yellow-green, a little to the right of Fraunhofer's line D. All the right side of the spectrum was green as far as the beginning of the violet, where it "ended with a sharp limit (about the line G)."

If you turn to the Report of the Royal Society's Committee[2] on Colour Vision, you will find the spectrum as it appears to yellow-blue-violet blind persons. The plate agrees with the description of Holmgren's case already given; but you will not find a representation of the spectrum as it appears to those who are red-green blind, and as described by Pole and others. In place of it you will find two dichromic spectra, one with a red and blue half said to be seen by a green blind, the other with a green and a blue half said to be seen by a red blind person. We have copied the spectra for your inspection, and you will observe that yellow does not appear in either of them. I do not for a moment pretend to criticize these spectra from any observations of my own; I am aware Holmgren maintains that red-and-green blindness may occur separately; but, on the other hand, Dr. George Berry, an eminent ophthalmologist, has assured me that he has always found them associated. That statement was originally made by Hering.

Of the various methods of testing colour vision, that suggested by Seebeck is most commonly employed. The individual is mainly tested with regard to his sense of green and red. He is shown skeins of wool, one pale green, another pink or purple, and a third bright red, and he is asked to select from a heap of coloured wools, laid on a white cloth, the colours that appear to him to match those of the several tests. We have arranged such test skeins for your inspection, and have placed beneath each of them the colours which a red-green blind person usually selects as having hues similar to those of the test. It is startling enough to find brown, orange, green, and grey confused with bright red; pale red, orange, yellow, and grey confused with green; blue, violet, and green confused with pink; but these confusions have all their explanation in the fact that the red-green blind have only two colour-sensations—yellow and blue, with a grey band in what should have been the green part of his spectrum.

We have now to show you another and far more beautiful method of ascertaining what fundamental colour sensations are absent in the colour-blind. It is the method of testing them by what Chevreul long ago termed *simultaneous contrast*. If in a semi-darkened room we throw a beam of coloured light on a white screen and interpose an opaque object in its path, the shadow shows the complementary colour. If the light be red, the shadow appears green-blue; if it be green, the shadow appears purple or red according to the nature of the green light employed. If the light is yellow, the shadow is blue; if it is blue, the shadow is yellow. We must remember that the part of the screen on which the shadow falls is not entirely dark; a little diffuse light falls on the retina from the shadowed part, so that the retina and vision centre are slightly stimulated, whereby the image of the shadow.

The experiment can be rendered still more striking, though at the same time a little more complicated, by using two oxy-hydrogen lamps and throwing their light on the same portion of the screen. If a plate of coloured—say ruby—glass is held before one of the lamps, and an opaque object such as the head of a T-square is placed in the path of both lights, the shadow cast by the white light falls on a surface illuminated by a red light, and shows a deep red far more saturated than the surrounding surface of the screen where the red and white lights fall. The shadow cast by the red light shows the complementary bluish green; and the contrast of the two is exceedingly striking.

These experiments we have shown you point to some subtle physiological relations between complementary colours. A colour sensation produced in one part of the vision apparatus forces, so to speak, the neighbouring part, which is relatively quiescent, to produce the complementary colour subjectively. I say *vision-centre* rather than *retina*, because, if one eye is illuminated with coloured light while the other eye is feebly illuminated with white light, the complementary colour appears in the centre belonging to that eye. The sense of white appears to be a mysterious unity; if you *objectively* call up one part of the sensation, you call up its counterpart *subjectively*. If a colour and its complementary counterpart be both displayed objectively at the same time, the action and reaction of effect afford a sensation far more agreeable than is producible by the objective display of only one of them. The agreeableness of the contrast of complementary colours, no doubt, springs from the harmony of effect. There is no harmony of colour effect analogous to that of music, but there is harmony of a different kind, and that harmony is formed by the contrast of complementary colours.

Now I imagine many of you have already anticipated the question, What information can simultaneous contrast give regarding the fundamental sensations of the colour-blind? From an extended series of observations Dr. Stilling,[1] of Cassel, has entertained that if a person cannot distinguish between red and green, no complementary colour appears in the shadow when the inducing light is red or green, but if the inducing light is yellow or blue the proper complementary appears in the shadow. If a person was blind to red he never found the complementary green appear; if he was blind to green, he never found the complementary red appear. When the inducing light appeared colourless, the shadow was also colourless. Stilling therefore concluded that either the sensations of red and green or of blue and yellow were wanting at the same time or all colour sense was absent. It is difficult to see how these results are to be harmonized with the conclusions arrived at by the Committee of the Royal Society.

Facts such as these are regarded by some as lending support to the theory of colour sense proposed by Prof. Hering, of Prague.[2] He supposes that the diversity of our visual perceptions arises from six fundamental sensations constituting three pairs—white and black, red and green, yellow and blue. The three pairs of sensations are supposed to arise from chemical changes in three visual substances not confined to the retina, but contained also in the optic nerve and in the vision centre.[3] He imagines that a sense of white results from *decomposition* induced in a special visual substance by all visible rays, and that the *restitution* of the same substance produces a sense of black. The sensations of the red and green pair are supposed to arise, the one from decomposition, the other from restitution of a second substance; while yellow and blue are supposed to result from decomposition and restitution of a third substance. From our knowledge of photo-chemical processes we can readily suppose that light induces chemical change in the visual apparatus; but that the wave-lengths in the red and yellow parts of the spectrum induce *decomposition*, while the wave-lengths in the green and blue induce *restitution* of substances, it is difficult to believe. How such a visual mechanism could work it would be difficult to comprehend; for example, if we look at a bright red light for a few moments and then close our eyes, the sensation remains for a time, but changes from red to green and then slowly fades away. According to Hering's theory, the green after-sensation results from the restitution of a substance decomposed by the red light. But if we reverse the experiment by looking at a bright *green* light and then closing our eyes, the after-sensation changes to *red*. The theory in question would require us to suppose that the green light builds up a visual substance which spontaneously decomposes when the eyes are closed, and so produces the red after-image. I confess that such a hypothesis seems to me incredible. Another remarkable feature of Hering's theory is that colours termed *complementary* ought to be termed *antagonistic*,[1] because they are capable of producing a colourless sensation when mingled in due proportions. If the complementary colours yellow and blue could, when mixed, produce black, they might well be named "antagonistic;" but since their combined effect is a sense of whiteness, and since the addition of them to white light increases its luminosity, it seems very difficult to comprehend on what ground the term *antagonistic* should be substituted for *complementary*. I confess I am quite unable to follow Hering when he supposes that three pairs of mutually antagonistic chemical processes are produced in the retina when white light falls on it, that these processes are all continued on through the optic nerve into the vision centre, and there give rise to our different light and colour sensations.

[3] Hering, *ibid.*, p. 75.

In 1881 Prof. Preyer[2] advanced a theory of colour sensation, in which he supposes that in the retina there are four sets of cones arranged in pairs—one pair being excitable by the waves in the blue and yellow parts of the spectrum, the other pair being excitable by the red and green. He supposes that each pair of cones is connected with a ganglionic cell in the retina, and through that with one fibre in the optic nerve, which transmits the impulse to at least two cells in the vision centre, in which two different qualities of sensation, red and green, yellow and blue, are severally produced. I confess, however, that I am not able to understand how nerve impulses received, say, from the red terminal of a pair, can specially affect one of the cells in the nerve centre to produce a red sensation. But if the red or green sensation were supposed to arise in the same central cell according to the frequency of the impulses transmitted from either terminal of the pair at the periphery, I should feel that an important difficulty had been removed from Prof. Preyer's theory.

It must be admitted that the production of nerve impulses within the terminals in the retina is almost as obscure as ever. It is still the old question, Does light stimulate the optic terminals by inducing vibration, or by setting up chemical change? Whichever view we adopt, it seems to me necessary to suppose that all the processes for the production of nerve impulses can take place in one and the same visual cell, and are transmitted to the brain through the same nerve fibre; because the image of a coloured star small enough to fall upon only one cone is seen of a fixed and definite colour which does not alter when the position of the eye is changed. It seems to me that if there are special cones for red, green, yellow, and blue, the colour of the star should change when its image falls on different terminals, but I am assured by Mr. Lockyer that such is not the case.

I referred to the sense of smell because it seems to me that we cannot in that case escape from the conclusion that the different sensations arise from different molecular stimulations of the same olfactory terminals.

From Lippmann's recent researches on the photography of colour[3] it appears that all parts of the spectrum can now be photographed on films of albumino-bromide of silver, to which two aniline substances, azaline and cyanine, have been added. It seems, therefore, reasonable to suppose that a relatively small number of substances could enable all the rays of the visible spectrum to affect the retina. Helmholz believes that three visual substances would suffice; but if the primary sensations are to be regarded as four—red, green, yellow, and blue—at least four visual substances appear to be necessary; and I think we must assume that all of them are to be found in the same visual cell in the retina, and that the nerve impulses which their decompositions give rise to are all transmitted through the same optic fibres to the brain cells, there to produce a sense of uncoloured or coloured light. Evidently such a hypothesis is not altogether novel; it is essentially a return to that long ago suggested by Newton. The only difference is that light is supposed to induce photo-chemical changes in the retina, as Von Helmholz suggested, instead of mere mechanical vibration, as Newton supposed. But if in the sense of smell nerve undulations are induced by mechanical vibrations of molecules acting on delicate hairs at the ends of cells, would it, after all, be unreasonable to suppose that within each visual cell there are different kinds of molecules that vibrate in different modes when excited by ether-waves? Four or five sets of such molecules in each terminal element in the retina would probably be sufficient to project successively or simultaneously special forms of undulations through the optic nerve, to induce colour sensations differing according to the wave form of the incoming nerve undulation. It seems to me that the question becomes narrowed down to this: Do the nerve impulses arise from mere vibration or from chemical change in the molecules of the nerve terminal? The photo-chemical hypothesis has much in its favour. We know how rapidly light can induce chemical change in photographic films, and we know that light induces chemical change in the vision-purple in the outer segments of the rod cells in the retina. The fact that the cones contain no vision-purple is no argument against the theory, for the inner segment of both rod and cone is by many regarded as the true nerve terminal, and there is no vision-purple in either of them. The visual substances in the cones, at all events, are colourless, and the existence of them as substances capable of producing nerve impulses by chemical decomposition is as yet only a speculation awaiting proof. The fatigue of the retina produced by bright light is best explained on a chemical theory, but it could also be explained on a mechanical theory, for we must remember that, even if the nerve impulses produced in the visual cells were merely a translation of the energy of light into vibration of nerve molecules, the nerve impulse has to pass through layers of ganglionic cells before reaching the fibres of the optic nerve, and in these cells it probably always induces chemical change. The phenomena of partial colour-blindness could be explained on a photo-chemical theory by supposing that it arises from the absence of the substances required to produce the wave forms necessary for the colour sensation which is defective, but the total colour blindness at the anterior part of the retina is evidently a difficulty. How could we have a sense of light from that portion of the retina if all the visual substances are absent? That is one of the reasons why Hering supposed that a special visual substance is present everywhere in the retina, which by decomposition gives rise to a sense of light as distinguished from colour. But even on the hypothesis we are pursuing, it is not necessary to suppose that all visual substance is absent, for colour-blindness in the front of the retina could be explained by supposing that colour perception has not been developed in the corresponding portion of the vision centre, and consequently all nerve impulses coming from that part of the retina produce scarcely anything more than a sense of light.

If the photo-chemical theory is entertained, it seems necessary to suppose that there is some singular relation between the pairs of substances which respectively give rise to red and green, and yellow and blue, seeing that both members of a pair frequently, if not always, fail together.

It seems to me that the great difficulty arises when we consider the puzzling phenomena of contrast. If light of a particular wave length decomposes a special substance, and gives rise to, say, a sense of red, why does the complementary bluish-green sensation appear in the vision centre around the spot in which the red sensation arises? If the induced colour were a pure green, one might attempt to explain it by supposing that a sympathetic change had been induced in a substance closely related to that suffering decomposition by the objective light, but no such simple explanation is admissible; the complementary contrast of red is not green, but a mixture of green and blue. The inadmissibility of such an explanation becomes still more apparent if we take pure green as the inducing colour—the complementary contrast that appears is purple, which involves a blue or violet, as well as a red sensation. It matters not what inducing colour sensation we adopt, the induced contrast is always the complementary required to make a sense of white. George Wilson[1] long ago suggested that the simultaneous contrast probably arises from a "polar manifestation of force;" indeed, he regarded it as a "true, though unrecognized, manifestation of polarity." It is enough to mention that interesting suggestion, but I must not pursue it, for we are dealing with a problem that has as yet baffled the wit of man.

I have endeavoured to place before you a subject that involves physical and physiological considerations of extreme difficulty. I have endeavoured to show the nature of these difficulties, and although I have not attempted to solve them, I have at all events tried to show reasons why we should refer our different colour sensations to differences in the incoming nerve impulses rather than to specifically different activities of cells in the visual centre. I have not found it an agreeable task to point out the shortcomings of theories advanced by those for whom I have the deepest regard; but in the progress of scientific thought it is especially necessary to keep our minds free from the thraldom of established theory, for theories are but the leaves of the tree of science; they bud and expand, and in time they fade and fall, but they enable the tree to breathe and live. If this address has been full of speculation, I trust you will allow that the scientific use of the imagination is a necessary stimulus to thought, by which alone we can break a path through the dense thicket of the unknown.

SECTION E.

GEOGRAPHY.

Opening Address by Prof. James Geikie, LL.D., D.C.L., F.R.SS.L. & E., F.G.S., President of the Section.

Amongst the many questions upon which of late years light has been thrown by deep-sea exploration and geological research not the least interesting is that of the geographical development of coast-lines. How is the existing distribution of land and water to be accounted for? Are the revolutions in the relative position of land and sea, to which the geological record bears witness, due to movements of the earth's crust or of the hydrosphere? Why are coast-lines in some regions extremely regular, while elsewhere they are much indented? About 150 years ago the prevalent belief was that ancient sea-margins indicated a formerly higher ocean-level. Such was the view held by Celsius, who, from an examination of the coast-lands of Sweden, attributed the retreat of the sea to a gradual drying up of the latter. But this desiccation hypothesis was not accepted by Playfair, who thought it much more likely that the land had risen. It was not, however, until after Von Buch had visited Sweden (1806–1808), and published the results of his observations, that Playfair's suggestion received much consideration. Von Buch concluded that the apparent retreat of the sea was not due to a general depression of the ocean-level, but to elevation of the land—a conclusion which subsequently obtained the strong support of Lyell. The authority of these celebrated men gained for the elevation theory more or less complete assent, and for many years it has been the orthodox belief of geologists that the ancient sea-margins of Sweden and other lands have resulted from vertical movements of the crust. It has long been admitted, however, that highly flexed and disturbed strata require some other explanation. Obviously such structures are the result of lateral compression and crumpling. Hence geologists have maintained that the mysterious subterranean forces have affected the crust in different ways. Mountain-ranges, they conceive, are ridged up by tangential thrusts and compression, while vast continental areas slowly rise and fall, with little or no disturbance of the strata. From this point of view it is the lithosphere that is unstable, all changes in the relative level of land and sea being due to crustal movements. Of late years, however, Trautschold and others have begun to doubt whether this theory is wholly true, and to maintain that the sea-level may have changed without reference to movements of the lithosphere. Thus Hilber has suggested that sinking of the sea-level may be due, in part at least, to absorption, while Schmick believes that the apparent elevation and depression of continental areas are really the results of grand secular movements of the ocean. The sea, according to him, periodically attains a high level in each hemisphere alternately, the waters being at present heaped up in the southern hemisphere. Prof. Suess, again, believing that in equatorial regions the sea is, upon the whole, gaining on the land, while in other latitudes the reverse would appear to be the case, points out that this is in harmony with his view of a periodical flux and reflux of the ocean between the equator and the poles. He thinks that we have no evidence of any vertical elevation affecting wide areas, and that the only movements of elevation that take place are those by which mountains are upheaved. The broad invasions and transgressions of the continental areas by the sea, which we know have occurred again and again, are attributed by him to secular movements of the hydrosphere itself.

Apart from all hypothesis and theory, we learn that the surface of the sea is not exactly spheroidal. It reaches a higher level on the borders of the continents than in mid-ocean, and it varies likewise in height at different places on the same coast. The attraction of the Himalaya, for example, suffices to cause a difference of 300 feet between the level of the sea at the delta of the Indus and on the coast of Ceylon. The recognition of such facts has led Penck to suggest that the submergence of the maritime regions of North-west Europe and the opposite coasts of North America, which took place at a recent geological date, and from which the lands in question have only partially recovered, may have been brought about by the attraction exerted by the vast ice-sheets of the Glacial Period. But, as Drygalski, Woodward, and others have shown, the heights at which recent marine deposits occur in the regions referred to are much too great to be accounted for by any possible distortion of the hydrosphere. The late James Croll had previously endeavoured to show that the accumulation of ice over northern lands during glacial times would suffice to displace the earth's centre of gravity, and thus cause the sea to rise upon the glaciated tracts. More recently other views have been advanced to explain the apparently causal connection between glaciation and submergence, but these need not be considered here.

Whatever degree of importance may attach to the various hypotheses of secular movements of the sea, it is obvious that the general trends of the world's coast-lines are determined in the first place by the position of the dominant wrinkles of the lithosphere. Even if we concede that all "raised beaches," so called, are not necessarily the result of earth-movements, and that the frequent transgressions of the continental areas by oceanic waters in geological times may possibly have been due to independent movements of the sea, still we must admit that the solid crust of the globe has always been subject to distortion. And this being so, we cannot doubt that the general trends of the world's coast-lines must have been modified from time to time by movements of the lithosphere.

As geographers we are not immediately concerned with the mode of origin of those vast wrinkles, nor need we speculate on the causes which may have determined their direction. It seems, however, to be the general opinion that the configuration of the lithosphere is due simply to the sinking in and crumpling up of the crust on the cooling and contracting nucleus. But it must be admitted that neither physicists nor geologists are prepared with a satisfactory hypothesis to account for the prominent trends of the great world-ridges and troughs. According to the late Prof. Alexander Winchell, these trends may have been the result of primitive tidal action. He was of opinion that the transmeridional progress of the tidal swell in early incrustive times on our planet would give the forming crust structural characteristics and aptitudes trending from north to south. The earliest wrinkles to come into existence, therefore, would be meridional or submeridional, and such, certainly, is the prevalent direction of the most conspicuous earth-features. There are many terrestrial trends, however, as Prof. Winchell knew, which do not conform to the requirements of his hypothesis; but such transmeridional features, he thought, could generally be shown to be of later origin than the others. This is the only speculation, so far as I know, which attempts, perhaps not altogether unsuccessfully, to explain the origin of the main trends of terrestrial features. According to other authorities, however, the area of the earth's crust occupied by the ocean is denser than that over which the continental regions are spread. The depressed denser part balances the lighter elevated portion. But why these regions of different densities should be so distributed no one has yet told us. Neither does Le Conte's view, that the continental areas and the oceanic depressions owe their origin to unequal radial contraction of the earth in its secular cooling, help us to understand why the larger features of the globe should be disposed as they are.

Geographers must for the present be content to take the world as they find it. What we do know is that our lands are distributed over the surface of a great continental plateau of irregular form, the bounding slopes of which plunge down more or less steeply into a vast oceanic depression. So far as geological research had gone, there is reason to believe that these elevated and depressed areas are of primeval antiquity—that they antedate the very oldest of the sedimentary formations. There is abundant evidence, however, to show that the relatively elevated or continental area has been again and again irregularly submerged under tolerably deep and wide seas. But all historical geology assures us that the continental plateau and the oceanic hollows have never changed places, although from time to time portions of the latter have been ridged up and added to the margins of the former, while ever and anon marginal portions of the plateau have sunk down to very considerable depths. We may thus speak of the great world-ridges as regions of dominant elevation, and of the profound oceanic troughs as areas of more or less persistent depression. From one point of view, it is true, no part of the earth's surface can be looked upon as a region of dominant elevation. Our globe is a cooling and contracting body, and depression must always be the prevailing movement of the lithosphere. The elevation of the continental plateau is thus only relative. Could we conceive the crust throughout the deeper portions of the oceanic depression to subside to still greater depths, while at the same time the continental plateau remained stationary, or subsided more slowly, the sea would necessarily retreat from the land, and the latter would then appear to rise. It is improbable, however, that any extensive subsidence of the crust under the ocean could take place without accompanying disturbance of the continental plateau; and in this case the latter might experience in places not only negative but positive elevation. During the evolution of our continent, crustal movements have again and again disturbed the relative level of land and sea, but since the general result has been to increase the land surface and to contract the area occupied by the sea, it is convenient to speak of the former as the region of dominant elevation, and of the latter as that of prevalent depression. Properly speaking, both are sinking regions, the rate of subsidence within the oceanic trough being in excess of that experienced over the continental plateau. The question of the geographical development of coast-lines is therefore only that of the dry lands themselves.

The greater land masses are all situated upon, but are nowhere coextensive with, the area of dominant elevation, for very considerable portions of the continental plateau are still covered by the sea. Opinions may differ as to which fathoms line we should take as marking approximately the boundary between that region and the oceanic depression; and it is obvious, indeed, that any line selected must be arbitrary and more or less misleading, for it is quite certain that the true boundary of the continental plateau cannot lie parallel to the surface of the ocean. In some regions it approaches within a few hundreds of fathoms of the sea-level; in other places it sinks for considerably more than 1000 fathoms below that level. Thus, while a very moderate elevation would in certain latitudes cause the land to extend to the edge of the plateau, an elevation of at least 10,000 feet would be required in some other places to bring about a similar result.

Although it is true that the land surface is nowhere coextensive with the great plateau, yet the existing coast-lines may be said to trend in the same general direction as its margins. So abruptly does the continental plateau rise from the oceanic trough, that a depression of the sea-level, or an elevation of the plateau, for 10,000 feet, would add only a narrow belt to the Pacific coast between Alaska and Cape Horn, while the gain of land on the Atlantic slope of America between 30° N.L. and 40° S.L. would not be much greater. In the higher latitudes of the Northern Hemisphere, however, very considerable geographical changes would be accomplished by a much less amount of elevation of the plateau. Were the continental plateau to be upheaved for 3000 feet, the major portion of the Arctic Sea would become land. Thus, in general terms, we may say that the coast-lines of Arctic and temperate North America and Eurasia are further withdrawn from the edge of the continental plateau than those of lower latitudes.

In regions where existing coast-lines approach the margin of the plateau, they are apt to run for long distances in one determinate direction, and whether the coastal area be high or not, to show a gentle sinuosity. Their course is seldom interrupted by bold projecting headlands or peninsulas, or by intruding inlets, while fringing or marginal islands rarely occur. To these appearances the northern regions, as every one knows, offer the strongest contrast. Not only do they trend irregularly, but their continuity is constantly interrupted by promontories and peninsulas, by inlets and fords, while fringing islands abound. But an elevation of some 400 or 500 fathoms only would revolutionize the geography of those regions, and confer upon the northern coast-lines of the world the regularity which at present characterizes those of Western Africa.

It is obvious, therefore, that the coast-lines of such lands as Africa owe their regularity primarily to their approximate coincidence with the steep boundary slopes of the continental plateau, while the irregularities characteristic of the coast-line of North-Western Europe and the corresponding latitudes of North America are determined by the superficial configuration of the same plateau, which in those regions is relatively more depressed. I have spoken of the general contrast between high and low northern latitudes, but it is needless to say that in southern regions the coast-lines exhibit similar contrasts. The regular coast-lines of Africa and South America have already been referred to, but we cannot fail to recognize in the much indented sea-board and the numerous coastal island of Southern Chili a complete analogy to the fiord regions of high northern latitudes. Both are areas of comparatively recent depression. Again, the manifold irregularities of the coasts of South-eastern Asia, and the multitudes of islands that serve to to link that continent to Australia and New Zealand, are all evidence that the surface of the continental plateau in those regions is extensively invaded by the sea.

A word or two now as to the configuration of the oceanic trough. There can be no doubt that this differs very considerably from that of the land surface. It is, upon the whole, flat or gently undulating. Here and there it swells gently upwards into broad elevated banks, some of which have been traced for great distances. In other places narrower ridges and abrupt mountain-like elevations diversify its surface, and project again and again above the level of the sea, to form the numerous islets of Oceania. Once more, the sounding-line has made us acquainted with the notable fact that numerous deep depressions—some long and narrow, others relatively short and broad—stud the floor of the great trough. I shall have occasion to refer again to these remarkable depressions, and need at present only call attention to the fact that they are especially well developed in the region of the Western Pacific, where the floor of the sea, at the base of the bounding slopes of the continental plateau, sinks in places to depths of three and even of five miles below the existing coast-lines. One may further note the fact that the deepest areas of the Atlantic are met with in like manner close to the walls of the plateau—a long ridge, which rises midway between the continents and runs in the same general direction as their coast-lines, serving to divide the trough of the Atlantic into two parallel hollows.

But, to return to our coast-lines and the question of their development, it is obvious that their general trends have been determined by crustal movements. Their regularity is in direct proportion to the closeness of their approach to the margin of the continental plateau. The more nearly they coincide with the edge of that plateau, the fewer irregularities do they present; the further they recede from it, the more highly are they indented. Various other factors, it is true, have played a more or less important part in their development, but their dominant trends were undoubtedly determined at a very early period in the world's history—their determination necessarily dates back, in short, to the time when the great world-ridges and oceanic troughs came into existence. So far as we can read the story told by the rocks, however, it would seem that in the earliest ages of which geology can speak with any confidence, the coast-lines of the world must have been infinitely more irregular than now. In Palæozoic times, relatively small areas of the continental plateau appeared above the level of the sea. Insular conditions everywhere prevailed. But as ages rolled on wider and wider tracts of the plateau were exposed, and this notwithstanding many oscillations of level. So that one may say there has been upon the whole a general advance from insular to continental conditions. In other words, the sea has continued to retreat from the surface of the continental plateau. To account for this change we must suppose that depression of the crust has been in excess within the oceanic area, and that now and again positive elevation of the continental plateau has taken place, more especially along its margins. That movements of elevation, positive or negative, have again and again affected our land areas can be demonstrated, and it seems highly probable, therefore, that similar movements may have been experienced with the oceanic trough.

Two kinds of crustal movement, as we have seen, are recognized by geologists. Sometimes the crust appears to rise, or, as the case may be, to sink over wide regions, without much disturbance or tilting of strata, although these are now and again more or less extensively fractured and displaced. It may conduce to clearness if we speak of these movements as regional. The other kind of crustal disturbance takes place more markedly in linear directions, and is always accompanied by abrupt folding and mashing together of strata, along with more or less fracturing and displacement. The plateau of the Colorado has often been cited as a good example of regional elevation, where we have a wide area of approximately horizontal strata apparently uplifted without much rock-disturbance, while the Alps or any other chain of highly flexed and convoluted strata will serve as an example of what we may term axial or linear uplifts. It must be understood that both regional and axial movements result from the same cause—the adjustment of the solid crust to the contracting nucleus—and that the term *elevation*, therefore, is only relative. Sometimes the sinking crust gets relief from the enormous lateral pressure to which it is subjected by ridging up along lines of weakness, and then mountains of elevation are formed; at other times, the pressure is relieved by the formation of broader swellings, when wide areas become uplifted relatively to surrounding regions. Geologists, however, are beginning to doubt whether upheaval of the latter kind can affect a broad continental area. Probably in most cases, the apparent elevation of continental regions is only negative. The land appears to have risen because the floor of the oceanic basin has become depressed. Even the smaller plateau-like elevations which occur within some continental regions may in a similar way owe their dominance to the sinking of contiguous regions.

In the geographical development of our land, movements of elevation and depression have played an important part. But we cannot ignore the work done by other agents of change. If the orographical features of the land everywhere attest the potency of plutonic agents, they no less forcibly assure us that the inequalities of surface resulting from such movement are universally modified by denudation and sedimentation. Elevated plains and mountains are gradually demolished, and the hollows and depressions of the great continental plateau become slowly filled with their detritus. Thus inland seas tend to vanish, inlets and estuaries are silted up, and the land in places advances seaward. The energies of the sea, again, come in to aid those of rain and river, so that under the combined action of all the superficial agents of change, the irregularities of coast-lines become reduced, and, were no crustal movement to intervene, would eventually disappear. The work accomplished by those agents upon a coast-line is most conspicuous in regions where the surface of the continental plateau is occupied by comparatively shallow seas. Here full play is given to sedimentation and marine erosion, while the latter alone comes into prominence upon shores that are washed by deeper waters. When the coast-lines advance to the edge of the continental plateau, they naturally trend, as we have seen, for great distances in some particular direction. Should they preserve that position, undisturbed by crustal oscillation, for a prolonged period of time, they will eventually be cut back by the sea. In this way a shelf or terrace will be formed, narrow in some places, broader in others, according to the resistance offered by the varying character of the rocks. But no long inlets or fiords can result from such action. At most the harder and less readily demolished rocks will form headlands, while shallow bays will be scooped out of the more yielding masses. In short, between the narrower and broader parts of the eroded shelf or terrace a certain proportion will tend to be preserved. As the shelf is widened, sedimentation will become more and more effective, and in places may come to protect the land from further marine erosion. This action is especially conspicuous in tropical and subtropical regions, which are characterized by well-marked rainy seasons. In such regions immense quantities of sediment are washed down from the land to the sea, and tend to accumulate along shore, forming low alluvial flats. All long-established coast-lines thus acquire a characteristically sinuous form, and perhaps no better examples could be cited than those of Western Africa.

To sum up, then, we may say that the chief agents concerned in the development of coast-lines are crustal movements, sedimentation, and marine erosion. All the main trends are the result of elevation and depression. Considerable geographical changes, however, have been brought about by the silting up of those shallow and sheltered seas which, in certain regions, overflow wide areas of the continental plateau. Throughout all the ages, indeed, epigene agents have striven to reduce the superficial inequalities of that plateau, by levelling heights and filling up depressions, and thus, as it were, flattening out the land surface and causing it to extend. The erosive action of the sea, from our present point of view, is of comparatively little importance. It merely adds a few finishing touches to the work performed by the other agents of change.

A glance at the geographical evolution of our own continent will render this sufficiently evident. Viewed in detail, the structure of Europe is exceedingly complicated, but there are certain leading features in its architecture which no profound analysis is required to detect. We note, in the first place, that highly disturbed rocks of Archæan and Palæozoic age reach their greatest development along the north-western and western borders of our continent, as in Scandinavia, the British Islands, North-west France, and the Iberian peninsula. Another belt of similarly disturbed strata of like age traverses Central Europe from west to east, and is seen in the South of Ireland, Cornwall, North-west France, the Ardennes, the Thüringerwald, the Erzgebirge, the Riesengebirge, the Böhmerwald, and other heights of Middle and Southern Germany. Strata of Mesozoic and Cainozoic age rest upon the older systems in such a way as to show that the latter had been much folded, fractured, and denuded before they came to be covered with younger formations. North and north-east of the central belt of ancient rocks just referred to, the sedimentary strata that extend to the shores of the Baltic and over a vast region in Russia, range in age from Palæozoic down to Cainozoic times, and are disposed for the most part in gentle undulations—they are either approximately horizontal or slightly inclined. Unlike the disturbed rocks of the maritime regions and of Central Europe, they have obviously been subjected to comparatively little folding since the time of their deposition. To the south of the primitive backbone of Central Europe succeeds a region composed superficially of Mesozoic and Cainozoic strata for the most part, which, along with underlying Palæozoic and Archæan rocks, are often highly flexed and ridged up, as in the chains of the Jura, the Alps, the Carpathians, &c. One may say, in general terms, that throughout the whole Mediterranean area Archæan and Palæozoic rocks appear at the surface only when they form the nuclei of mountains of elevation into the composition of which rocks of younger age largely enter.

From this bald and meagre outline of the general geological structure of Europe, we may gather that the leading orographical features of our continent began to be developed at a very early period. Unquestionably the oldest land areas are represented by the disturbed Archæan and Palæozoic rocks of the Atlantic sea-board and Central Europe. Examination of those tracts shows that they have experienced excessive denudation. The Archæan and Palæozoic masses, distributed along the margin of the Atlantic, are the mere wrecks of what, in earlier ages, must have been lofty regions, the mountain-chains of which may well have rivalled or even exceeded in height the Alps of to-day. They, together with the old disturbed rocks of Central Europe, formed for a long time the only land in our area. Between the ancient Scandinavian tract in the north and a narrow interrupted belt in Central Europe stretched a shallow sea, which covered all the regions that now form our Great Plain; while immediately south of the central belt lay the wide depression of the Mediterranean—for as yet the Pyrenees, the Alps, and the Carpathians were not. Both the Mediterranean and the Russo-Germanic sea communicated with the Atlantic. As time went on, land continued to be developed along the same lines, a result due partly to crustal movements, partly to sedimentation. Thus by and by the relatively shallow Russo-Germanic sea became silted up, while the Mediterranean shore-line advanced southwards. It is interesting to note that the latter sea, down to the close of Tertiary times, seems always to have communicated freely with the Atlantic, and to have been relatively deep. The Russo-Germanic sea, on the contrary, while now and again opening widely into the Atlantic, and attaining considerable depths in its western reaches, remained on the whole shallow, and ever and anon vanished from wide areas to contract into a series of inland seas and large salt lakes.

Reduced to its simplest elements, therefore, the structure of Europe shows two primitive ridges—one extending with some interruptions along the Atlantic sea-board, the other traversing Central Europe from west to east, and separating the area of the Great Plain from the Mediterranean basin. The excessive denudation which the more ancient lands have undergone, and great uplifts of Mesozoic and of Cainozoic times, together with the comparatively recent submergence of broad tracts in the north and north-west, have not succeeded in obscuring the dominant features in the architecture of our continent.

I now proceed to trace, as rapidly as I can, the geographical development of the coast-lines of the Atlantic as a whole, and to point out the chief contrasts between them and those of the Pacific. The extreme irregularity of the Arctic and Atlantic shores of Europe at once suggests to a geologist a partially drowned land, the superficial inequalities of which are accountable for the vagaries of the coast-lines. The fiords of Norway and Scotland occupy what were at no distant date land valleys, and the numerous marginal islands of those regions are merely the projecting portions of a recently sunken area. The continental plateau extends up to and a little beyond the one hundred fathoms line, and there are many indications that the land formerly reached as far. Thus the sunken area is traversed by valley-like depressions, which widen as they pass out to the edge of the plateau, and have all the appearance of being hollows of subaerial erosion. I have already mentioned the fact that the Scandinavian uplands and the Scottish Highlands are the relics of what were at one time true mountains of elevation, corresponding in the mode of their formation to those of Switzerland, and, like these, attaining a great elevation. During subsequent stages of Palæozoic time, that highly elevated region was subjected to long-continued and profound erosion—the mountain country was planed down over wide regions to sea-level, and broad stretches of the reduced land surface became submerged. Younger Palæozoic formations now accumulated upon the drowned land, until eventually renewed crustal disturbance supervened, and the marginal areas of the continental plateau again appeared as dry land, but not, as before, in the form of mountains of elevation. Lofty table-lands now took the place of abrupt and serrated ranges and chains—table-lands which, in their turn, were destined in the course of long ages to be deeply sculptured and furrowed by subaerial agents. During this process the European coast-line would seem to have coincided more or less closely with the edge of the continental plateau. Finally, after many subsequent movements of the crust in these latitudes, the land became partially submerged—a condition from which North-western and Northern [Europe would appear in recent times to be slowly recovering. Thus the highly indented coast-line of those regions does not coincide with the edge of the plateau, but with those irregularities of its upper surface which are the result of antecedent subaerial erosion.

Mention has been made of the Russo-Germanic plain and the Mediterranean as representing original depressions in the continental plateau, and of the high grounds that extend between them as regions of dominant elevation, which, throughout all the manifold revolutions of the past, would appear to have persisted as a more or less well-marked boundary, separating the northern from the southern basin. During certain periods it was no doubt in some degree submerged, but never apparently to the same extent as the depressed areas it served to separate. From time to time uplifts continued to take place along this central belt, which thus increased in breadth, the younger formations, which were accumulated along the margins of the two basins, being successively ridged up against nuclei of older rocks. The latest great crustal movements in our continent, resulting in the uplift of the Alps and other east and west ranges of similar age, have still further widened that ancient belt of dominant elevation which in our day forms the most marked orographical feature of Europe.

The Russo-Germanic basin is now for the most part land, the Baltic and the North Sea representing its still submerged portions. This basin, as already remarked, was probably never so deep as that of the Mediterranean. We gather as much from the fact that, while mechanical sediments of comparatively shallow-water origin predominate in the former area, limestones are the characteristic features of the southern region. Its relative shallowness helps us to understand why the northern depression should have been silted up more completely than the Mediterranean. We must remember also that for long ages it received the drainage of a much more extensive land surface than the latter—the land that sloped towards the Mediterranean in Palæozoic and Mesozoic times being of relatively little importance. Thus the crustal movements which ever and anon depressed the Russo-Germanic area were, in the long run, counterbalanced by sedimentation. The uplift of the Alps, the Atlas, and other east and west ranges, has greatly contracted the area of the Mediterranean, and sedimentation has also acted in the same direction, but it is highly probable that that sea is now as deep as, or even deeper than, it has ever been. It occupies a primitive depression in which the rate of subsidence has exceeded that of sedimentation. In many respects, indeed, this remarkable transmeridional hollow—continued eastward in the Red Sea, the Black Sea, and the Aralo-Caspian depression—is analogous, as we shall see, to the great oceanic trough itself.

In the earlier geological periods linear or axial uplifts and volcanic action again and again marked the growth of the land on the Atlantic sea-board. But after Palæozoic times, no great mountains of elevation came into existence in that region, while volcanic action almost ceased. In Tertiary times, it is true, there was a remarkable recrudescence of volcanic activity, but the massive eruptions of Antrim and Western Scotland, of the Færöe Islands and Iceland, must be considered apart from the general geology of our continent. From Mesozoic times onwards it was along the borders of the Mediterranean depression that great mountain uplifts and volcanoes chiefly presented themselves. And as the land surface extended southwards from Central Europe, and the area of the Mediterranean was contracted, volcanic action followed the advancing shore-lines. The occurrence of numerous extinct and of still existing volcanoes along the borders of this inland sea, the evidence of recent crustal movements so commonly met with upon its margins, the great irregularities of its depths, the proximity of vast axial uplifts of late geological age, and the frequency of earthquake phenomena, all indicate instability, and remind us strongly of similarly constructed and disturbed regions within the area of the vast Pacific.

Let us now look at the Arctic and Antarctic coast-lines of North America. From the extreme north down to the latitude of New York the shores are obviously those of a partially submerged region. They are of the same type as the coasts of North-western Europe. We have every reason to believe also that the depression of Greenland and North-east America, from which these lands have only partially recovered, dates back to a comparatively recent period. The fiords, and inlets, like those of Europe, are merely half-drowned land valleys, and the continental shelf is crossed by deep hollows which are evidently only the seaward continuations of well-marked terrestrial features. Such, for example, is the case with the valleys of the Hudson and the St. Lawrence, the submerged portions of which can be followed out to the edge of the continental plateau, which is notched by them at depths of 474 and 622 fathoms respectively. There is, in short, a broad resemblance between the coasts of the entire Arctic and North Atlantic regions down to the latitudes already mentioned. Everywhere they are irregular and fringed with islands in less or greater abundance—highly denuded and deeply incised plateaus being penetrated by fiords, while low-lying and undulating lands that shelve gently seaward are invaded by shallow bays and inlets. Comparing the American with the opposite European coasts, one cannot help being struck with certain other resemblances. Thus Hudson Bay at once suggests the Baltic, and the Gulf of Mexico, with the Caribbean Sea, recall the Mediterranean. But the geological structure of the coast-lands of Greenland and North America betrays a much closer resemblance between these and the opposite shores of Europe than appears on a glance at the map. There is something more than a mere superficial similarity. In eastern North America and Greenland, just as in Western Europe, no grand mountain uplifts have taken place for a prodigious time. The latest great upheavals, which were accompanied by much folding and flexing of strata, are those of the Appalachian chain and of the coastal ranges extending through New England, Nova Scotia, and Newfoundland, all of which are of Palæozoic age. Considerable crustal movements affected the American coast-lands in Mesozoic times, and during these uplifts the strata suffered fracture and displacement, but were subjected to comparatively little folding. Again, along the maritime borders of North-east America, as in the corresponding coast-lands of Europe, igneous action, more or less abundant in Palæozoic and early Mesozoic times, has since been quiescent. From the mouth of the Hudson to the Straits of Florida the coast-lands are composed of Tertiary and Quaternary deposits. This shows that the land has continued down to recent times to gain upon the sea—a result brought about partly by quiet crustal movements, but to a large extent by sedimentation, aided, on the coasts of Florida, by the action of reef-building corals.

Although volcanic action has long ceased on the American sea-board, we note that in Greenland, as in the West of Scotland and North of Ireland, there is abundant evidence of volcanic activity at so late a period as the Tertiary. It would appear that the great plateau-basalts of those regions, and of Iceland and the Færöe Islands, were contemporaneous, and possibly connected with an important crustal movement. It has long been suggested that at a very early geological period Europe and North America may have been united. The great thickness attained by the Palæozoic rocks in the eastern areas of the latter implies the existence of a wide land surface from which ancient sediments were derived. That old land must have extended beyond the existing coast-line, but how far we cannot tell. Similarly in North-west Europe, during early Palæozoic times, the land probably stretched further into the Atlantic than at present. But whether, as some think, an actual land connection subsisted between the two continents it is impossible to say. Some such connection was formerly supposed necessary to account for the emigration and immigration of certain marine forms of life which are common to the Palæozoic strata of both continents, and which, as they were probably denizens of comparatively shallow water, could only have crossed from one area to another along a shore-line. It is obvious, indeed, that if the oceanic troughs in those early days were of an abysmal character, a land bridge would be required to explain the geographical distribution of cosmopolitan life-forms. But if it be true that subsidence of the crust has been going on through all geological time, and that the land areas have notwithstanding continued to extend over the continental plateau, then it follows that the oceanic trough must be deeper now than it was in Palæozoic times. There are, moreover, certain geological facts which seem hardly explicable on the assumption that the seas of past ages attained abysmal depths over any extensive areas. The Palæozoic strata which enter so largely into the framework of our lands have much the same appearance all the world over, and were accumulated for the most part in comparatively shallow water. A petrographical description of the Palæozoic mechanical sediments of Europe would serve almost equally well for those of America, of Asia, or of Australia. Take in connection with this the fact that Palæozoic faunas had a very much wider range than those of Mesozoic and later ages, and were characterized above all by the presence of many cosmopolitan species, and we can hardly resist the conclusion that it was the comparative shallowness of the ancient seas that favoured that wide dispersal of species, and enabled currents to distribute sediments the same in kind over such vast regions. As the oceanic area deepened and contracted, and the land surface increased, marine faunas were gradually restricted in their range, and cosmopolitan marine faunas diminished in numbers, while sediments, gathering in separate regions, became more and more differentiated. For these and other reasons, which need not be entered upon here, I see no necessity for supposing that a Palæozoic Atlantis connected Europe with North America. The broad ridge upon which the Færöe Islands and Iceland are founded, seems to pertain as truly to the oceanic depression as the long Dolphin Ridge of the South Atlantic. The trend of the continental plateau in high latitudes is shown, as I think, by the general direction of the coast-lines of North-Western Europe and East Greenland, the continental shelf being submerged in those regions for a few hundred fathoms only. How the Icelandic ridge came into existence, and what its age may be, we can only conjecture. It may be a wrinkle as old as the oceanic trough which it traverses, or its origin may date back to a much more recent period. We may conceive it to be an area which has subsided more slowly than the floor of the ocean to the north and south; or, on the other hand, it may be a belt of positive elevation. Perhaps the latter is the more probable supposition, for it seems very unlikely that crustal disturbances, resulting in axial and regional uplifts, should have been confined to the continental plateau only. Be that as it may, there seems little doubt that land connection did obtain between Greenland and Europe in Cainozoic times, along this Icelandic ridge, for relics of the same Tertiary flora are found in Scotland, the Færöe Islands, Iceland, and Greenland. The deposits in which these plant-remains occur are associated with great sheets of volcanic rocks which in the Færöe Islands and Iceland reach a thickness of many thousand feet. Of the same age are the massive basalts of Jan Mayen, Spitzbergen, Franz Joseph Land, and Greenland. These lavas seem seldom to have issued from isolated foci in the manner of modern eruptions, but rather to have welled up along the lines of rectilineal fissures. From the analogy of similar phenomena in other parts of the world it might be inferred that the volcanic action of these northern regions may have been connected with a movement of elevation, and that the Icelandic ridge, if it did not come into existence during the Tertiary period, was at all events greatly upheaved at that time. It would seem most likely, in short, that the volcanic action in question was connected mainly with crustal movements in the oceanic trough. Similar phenomena, as is well known, are met with further south in the trough of the Atlantic. Thus the volcanic Azores rise like Iceland from the surface of a broad ridge which is separated from the continental plateau by wide and deep depressions. And so again, from the back of the great Dolphin Ridge, spring the volcanic islets of St. Paul's, Ascension, and Tristan d'Acunha.

I have treated of the Icelandic bank at some length for the purpose of showing that its volcanic phenomena do not really form an exception to the rule that such eruptions ceased after Palæozoic or early Mesozoic times to disturb the Atlantic coast-lines of Europe and North America. As the bank in question extends between Greenland and the British Islands, it was only natural that both those regions should be affected by its movements. But its history pertains essentially to that of the Atlantic trough; and it seems to show how transmeridional movements of the crust, accompanied by vast discharges of igneous rock, may come in time to form land connections between what are now widely separated areas.

Let us next turn our attention to the coast-lines of the Gulf of Mexico and the Caribbean Sea. These enclosed seas have frequently been compared to the Mediterranean, and the resemblance is self-evident. Indeed, it is so close that one may say the Mexican-Caribbean Sea and the Mediterranean are rather homologous than simply analogous. The latter, as we have seen, occupies a primitive depression, and formerly covered a much wider area. It extended at one time over much of Southern Europe and Northern Africa, and appears to have had full communication across Asia Minor with the Indian Ocean, and with the Arctic Ocean athwart the low-lying tracts of North-Western Asia. Similarly, it would seem, the Mexican-Caribbean Sea is the remaining portion of an ancient inland sea which formerly stretched north through the heart of North America to the Arctic Ocean. Like its European parallel, it has been diminished by sedimentation and crustal movements. It resembles the latter also in the greatness and irregularity of its depths, and in the evidence which its islands supply of volcanic action as well as of very considerable crustal movements within geological times. Along the whole northern borders of the Gulf of Mexico the coast-lands, like those on the Atlantic seaboard of the Southern States, are composed of Tertiary and recent accumulations, and the same is the case with Yucatan; while similar young formations are met with on the borders of the Caribbean Sea and the Antilles. The Bahamas and the Windward Islands mark out for us the margin of the continental plateau, which here falls away abruptly to profound depths. One feels assured that this portion of the plateau has been ridged up to its present level at no distant geological date. But notwithstanding all the evidence of recent extensive crustal movements in this region, it is obvious that the Mexican-Caribbean depression, however much it may have been subsequently modified, is of primitive origin.[1]

Before we leave the coast-lands of North America, I would again point out their leading geological features. In a word, then, they are composed for the most part of Archæan and Palæozoic rocks; no great linear or axial uplifts marked by much flexure of strata have taken place in those regions since Palæozoic times; while igneous action virtually ceased about the close of the Palæozoic or the commencement of the Mesozoic period. It is not before we reach the shores of the Southern States and the coast-lands of the Mexican-Caribbean Sea that we encounter notable accumulations of Mesozoic, Tertiary, and younger age. These occur in approximately horizontal positions round the Gulf of Mexico, but in the Sierra Nevada or Northern Colombia and the Cordilleras of Venezuela Tertiary strata are ridged up into true mountains of elevation. Thus the Mexican-Caribbean depression, like that of the Mediterranean, is characterized not only by its irregular depths and its volcanic phenomena, but by the propinquity of recent mountains of upheaval, which bear the same relation to the Caribbean Sea that the mountains of North Africa do to the Mediterranean.

---

[1] Professor Suess thinks it is probable that the Caribbean Sea and the Mediterranean are portions of one and the same primitive depression which traversed the Atlantic area in early Cretaceous times. He further suggests that it may have been through the gradual widening of this central Mediterranean that the Atlantic in later times came into existence.

We may now compare the Atlantic coasts of South America with those of Africa. The former coincide in general direction with the edge of the continental plateau, to which they closely approach between Cape St. Roque and Cape Frio. In the north-east, between Cape Paria, opposite Trinidad, and Cape St. Roque, the continental shelf attains a considerably greater breadth, while south of Cape Frio it gradually widens, until, in the extreme south, it runs out towards the east in the form of a narrow ridge, upon the top of which rise the Falkland Islands and South Georgia. Excluding from consideration for the present all recent alluvial and Tertiary deposits, we may say that the coast lands from Venezuela down to the South of Brazil are composed principally of Archæan rocks; the eastern borders of the continent further south being formed of Quaternary and Tertiary accumulations. So far as we know, igneous rocks are of rare occurrence on the Atlantic sea-board. Palæozoic strata approach the coast-lands at various points between the mouths of the Amazons and La Plata, and these, with the underlying and surrounding Archæan rocks, are more or less folded and disturbed, while the younger strata of Mesozoic and Cainozoic age (occupying wide regions in the basin of of the Amazons, and here and there fringing the sea-coast), occur in approximately horizontal positions. It would appear, therefore, that no great axial uplifts have taken place in those regions since Palæozoic times. The crustal movements of later ages were regional rather than axial; the younger rocks are not flexed and mashed together, and their elevation (negative or positive) does not seem to have been accompanied by conspicuous volcanic action.

The varying width of the continental shelf is due to several causes. The Orinoco, the Amazons, and other rivers descending to the north-west coast, carry enormous quantities of sediment, much of which comes to rest on the submerged slopes of the continental plateau, so that the continental shelf tends to extend seawards. The same process takes place on the south-east coast, where the River Plate discharges its muddy waters. South of latitude 40° S., however, another cause has come into play. From the mouth of the Rio Negro to the terminal point of the continent the whole character of the coast betokens a geologically recent emergence, accompanied and followed by considerable marine erosion. So that in this region the continental shelf increases in width by the retreat of the coast-line, while in the north-east it gains by advancing seawards. It is to be noted, however, that even there, in places where the shores are formed of alluvia, the sea tends to encroach upon the land.

The Atlantic coast of Africa resembles that of South America in certain respects, but it also offers some important contrasts. As the northern coasts of Venezuela and Colombia must be considered in relation rather to the Caribbean depression than to the Atlantic, so the African sea-board between Cape Spartel and Cape Nun pertains structurally to the Mediterranean region. From the southern limits of Morocco to Cape Colony the coastal heights are composed chiefly of Archæan and Palæozoic rocks, the low shore-lands showing here and there strata of Mesozoic and Tertiary age together with still more recent deposits. The existing coast-lines everywhere advance close to the edge of the continental plateau, so that the submarine shelf is relatively narrower than that of Eastern South America. The African coast is still further distinguished from that of South America by the presence of several groups of volcanic islands—Fernando Po and others in the Gulf of Guinea, and Cape Verde and Canary Islands. The last-named group, however, notwithstanding its geographical position, is probably related rather to the Mediterranean depression than to the Atlantic trough.

The geological structure of the African coast-lands shows that the earliest to come into existence were those that extend between Cape Nun and the Cape of Good Hope. The coastal ranges of that section are much denuded, for they are of very great antiquity, having been ridged up in Palæozoic times. The later uplifts (negative or positive) of the same region were not attended by tilting and folding of strata, for the Mesozoic and Tertiary deposits, like those of South America, lie in comparatively horizontal positions. Between Cape Nun and Cape Spartel the rocks of the maritime tracts range in age from Palæozoic to Cainozoic, and have been traced across Morocco into Algeria and Tunis. They all belong to the Mediterranean region, and were deposited at a time when the southern shores of that inland sea extended from a point opposite the Canary Islands along the southern margin of Morocco, Algeria, and Tunis. Towards the close of the Tertiary period the final upheaval of the Atlas took place, and the Mediterranean, retreating northwards, became an almost land-locked sea.

I need hardly stop to point out how the African coast-lines have been modified by marine erosion and the accumulation of sediment upon the continental shelf. The extreme regularity of the coasts is due partly to the fact that the land is nearly coextensive with the continental plateau, but it also results in large measure from the extreme antiquity of the land itself. This has allowed of the cutting-back of headlands and the filling-up of bays and inlets, a process which has been going on between Morocco and Cape Colony with probably little interruption for a very prolonged period of time. We may note also the effect of the heavy rains of the equatorial region in washing down detritus to the shores, and in this way protecting the land to some extent from the erosive action of the sea.

What now, let us ask, are the outstanding features of the coast-lines of the Atlantic Ocean? We have seen that along the margins of each of the bordering continents the last series of great mountain-uplifts took place in Palæozoic times. This is true alike for North and South America, for Europe and Africa. Later movements which have added to the extent of land were not marked by the extreme folding of strata which attended the early upheavals. The Mesozoic and Cainozoic rocks, which now and again form the shore-lands, occur in more or less undisturbed condition. The only great linear uplifts or true mountains of elevation which have come into existence in Western Europe and Northern Africa since the Palæozoic period trend approximately at right angles to the direction of the Atlantic trough, and are obviously related to the primitive depression of the Mediterranean. The Pyrenees and the Atlas, therefore, although their latest elevation took place in Tertiary times, form no exceptions to the rule that the extreme flexing and folding of strata which is so conspicuous a feature in the geological structure of the Atlantic sea-board dates back to the Palæozoic era. And the same holds true of North and South America. There all the coastal ranges of highly flexed and folded strata are of Palæozoic age. The Cordilleras of Venezuela are no doubt a Tertiary uplift, but they are as obviously related to the Caribbean depression as the Atlas ranges are to that of the Mediterranean. Again, we note that volcanic activity along the borders of the Atlantic was much less pronounced during the Mesozoic period than it appears to have been in earlier ages. Indeed, if we except the great Tertiary basalt-flows of the Icelandic ridge and the Arctic regions, we may say that volcanic action almost ceased after the Palæozoic era to manifest itself upon the Atlantic coast-lands of North America and Europe. But while volcanic action has died out upon the Atlantic margins of both continents, it has continued during a prolonged geological period within the area of the Mediterranean depression. And in like manner the corresponding depression between North and South America has been the scene of volcanic disturbances from Mesozoic down to recent times. Along the African coasts the only displays of recent volcanic action that appertain to the continental margin are those of the Gulf of Guinea and the Cape de Verde Islands. The Canary Islands and Madeira may come under the same category, but, as we have seen, they appear to stand in relationship to the Mediterranean depression and the Tertiary uplift of North Africa. Of Iceland and the Azores I have already spoken, and of Ascension and the other volcanic islets of the South Atlantic it is needless to say that they are related to wrinkles in the trough of the ocean, and therefore have no immediate connection with the continental plateau.

Thus in the geographical development of the Atlantic coast-lines we may note the following stages:—*First*, during Palæozoic times a series of great mountain-uplifts, which were frequently accompanied by volcanic action. *Second*, a prolonged stage of comparative coastal tranquillity, during which the maritime ranges referred to were subject to such excessive erosion that they were planed down to low levels, and in certain areas even submerged. *Third*, renewed elevation (negative or positive) whereby considerable portions of the much denuded Archæan and Palæozoic rocks, now largely covered by younger deposits, were converted into high lands. During this stage not much rock-folding took place, nor were any true mountains of elevation formed parallel to the Atlantic margins. It was otherwise, however, in the Mediterranean and Caribbean depressions, where coastal movements resulted in the formation of enormous linear uplifts. Moreover, volcanic action is now and has for a long time been more characteristic of these depressions than of the Atlantic coast-lands.

I must now ask you to take a comprehensive glance at the coast-lines of the Pacific Ocean. In some important respects these offer a striking contrast to those we have been considering. Time will not allow me to enter into detailed description, and I must therefore confine attention to certain salient features. Examining first the shores of the Americas, we find that there are two well-marked regions of fiords and fringing islands—namely, the coasts of Alaska and British Columbia, and of South America from 40° S.L. to Cape Horn. Although these regions may be now extending seawards in places, it is obvious that they have recently been subject to submergence. When the fiords of Alaska and British Columbia existed as land valleys it is probable that a broad land connection obtained between North America and Asia. The whole Pacific coast is margined by mountain ranges, which in elevation and boldness far exceed those of the Atlantic sea-board. The rocks entering into their formation range in age from Archæan and Palæozoic, and they are almost everywhere highly disturbed and flexed. It is not necessary, even if it were possible, to consider the geological history of all those uplifted masses. It is enough for my purpose to note the fact that the coastal ranges of North America and the principal chain of the Andes were all elevated in Tertiary times. It may be remarked further, that from the Mesozoic period down to the present the Pacific borders of America have been the scene of volcanic activity far in excess of what has been experienced on the Atlantic sea-board.

Geographically the Asiatic coasts of the Pacific offer a strong contrast to those of the American borders. The latter, as we have seen, are for the most part not far removed from the edge of the continental plateau. The coasts of the mainland of Asia, on the other hand, retire to a great distance, the true margin of the plateau being marked out by that great chain of islands which extends from Kamchatka south to the Philippines and New Guinea. The seas lying between those islands and the mainland occupy depressions in the continental plateau. Were that plateau to be lifted up for 6,000 or 7,000 feet the seas referred to would be enclosed by continuous land, and all the principal islands of the Indian Archipelago—Sumatra, Java, Celebes, and New Guinea, would become united to themselves as well as to Australia and New Zealand. In short, it is the relatively depressed condition of the continental plateau along the western borders of the Pacific basin that caused the Asiatic coast-lines to differ so strikingly from those of America.

From a geological point of view the differences are less striking than the resemblances. It is true that we have as yet a very imperfect knowledge of the geological structure of Eastern Asia, but we know enough to justify the conclusion that in its main features that region does not differ essentially from Western North America. During Mesozoic and Cainozoic times the sea appears to have overflowed vast tracts of Manchooria and China, and even to have penetrated into what is now the great Desert of Gobi. Subsequent crustal movements revolutionised the geography of all those regions. Great ranges of linear uplifts came into existence, and in these the younger formations, together with the foundations on which they rested, were squeezed into folds and ridged up against the nuclei of Palæozoic and Archæan rocks which had hitherto formed the only dry land. The latest of these grand upheavals are of Tertiary age, and, like those of the Pacific slope of America, they were accompanied by excessive volcanic action. The long chains of islands that flank the shores of Asia we must look upon as a series of partially submerged or partially emerged mountain-ranges, analogous geographically to the coast ranges of North and Central America, and to the youngest Cordilleras of South America. The presence of numerous active and recently extinct volcanoes, taken in connection with the occurrence of many great depressions which furrow the floor of the sea in the East Indian Archipelago, and the profound depths attained by the Pacific trough along the borders of Japan and the Kurile and Aleutian Islands—all indicate conditions of very considerable instability of the lithosphere. We are not surprised, therefore, to meet with much apparently conflicting evidence of elevation and depression in the coast-lands of Eastern Asia, where in some places the sea would seem to be encroaching, while in other regions it is retreating. In all earthquake-ridden and volcanic areas such irregular coastal changes may be looked for. So extreme are the irregularities of the sea-floor in the area lying between Australia, the Solomon Islands, the New Hebrides, and New Zealand, and so great are the depths attained by many of the depressions, that the margins of the continental plateau are harder to trace here than anywhere else in the world. The bottom of the oceanic trough throughout a portion of the Southern and Western Pacific is, in fact, traversed by many great mountain rides, the summits of which approach the surface again and again to form the numerous islets of Polynesia. But notwithstanding the considerable depths that separate Australia and New Zealand there is geological evidence to show that a land connection formerly linked both to Asia. The continental plateau, therefore, must be held to include New Caledonia and New Zealand. Hence the volcanic islets of the Solomon and New Hebrides groups are related to Australia in the same way as the Riu-kiu, Japanese, and Kurile Islands are to Asia.

Having rapidly sketched the more prominent features of the Pacific coast-lines, we are in a position to realise the remarkable contrast they present to the coast-lines of the Atlantic. The highly folded strata of the Atlantic sea-board are the relics of great mountains of upheaval, the origin of which cannot be assigned to a more recent date than Palæozoic times. During subsequent crustal movements no mountains of corrugated strata were uplifted along the Atlantic margins, the Mesozoic and Cainozoic strata of the coastal regions showing little or no disturbance. It is quite in keeping with all this that volcanic action appears to have been most strongly manifested in Palæozoic times. So many long ages have passed since the upheaval of the Archæan and Palæozoic mountains of the Atlantic sea-board that these heights have everywhere lost the character of true mountains of elevation. Planed down to low levels, partially submerged and covered to some extent by newer formations, they have in many places been again converted into dry lands, forming plateaus—now sorely denuded and cut up into mountains and valleys of erosion. Why the later movements along the borders of the Atlantic basin should not have resulted in the wholesale plication of the younger sedimentary rocks is a question for geologists. It would seem as if the Atlantic margins had reached a stage of comparative stability long before the grand Tertiary uplifts of the Pacific borders had taken place; for, as we have seen, the Mesozoic and Cainozoic strata of the Atlantic coast-lands show little or no trace of having been subjected to tangential thrusting and crushing. Hence one cannot help suspecting that the retreat of the sea during Mesozoic and Cainozoic ages may have been due rather to subsidence of the oceanic trough and to sedimentation within the continental area than to positive elevation of the land.

Over the Pacific trough, likewise, depression has probably been in progress more or less continuously since Palæozoic times, and this movement alone must have tended to withdraw the sea from the surface of the continental plateau in Asia and America. But by far the most important coastal changes in those regions have been brought about by the crumpling up of the plateau, and the formation of gigantic mountains of upheaval along its margins. From remotest geological periods down almost to the present the land area has been increased from time to time by the doubling-up and consequent elevation of coastal accumulations and by the eruption of vast masses of volcanic materials. It is this long-continued activity of the plutonic forces within the Pacific area which has caused the coast-lands of that basin to contrast so strongly with those of the Atlantic. The latter are incomparably older than the former—the heights of the Atlantic borders being mountains of denudation of vast geological antiquity, while the coastal ranges of the Pacific slope are creations but of yesterday as it were. It may well be that those Cordilleras and mountain-chains reach a greater height than was ever attained by any Palæozoic uplifts of the Atlantic borders. But the marked disparity in elevation between the coast-lands of the Pacific and the Atlantic is due chiefly to a profound difference in age. Had the Pacific coast-lands existed for as long a period and suffered as much erosion as the ancient rocks of the Atlantic sea-board, they would now have little elevation to boast of.

The coast-lines of the Indian Ocean are not, upon the whole, far removed from the margin of the continental plateau. The elevation of East Africa for 6000 feet would add only a very narrow belt to the land. This would still leave Madagascar an island, but there are geological reasons for concluding that this island was at a far distant period united to Africa, and it must therefore be considered as forming a portion of the continental plateau. The great depths which now separate it from the mainland are probably due to local subsidence, connected with volcanic action in Madagascar itself and in the Comoro Islands. The southern coasts of Asia, like those of East Africa, approach the edge of the continental plateau, so that an elevation of 6000 feet would make little addition to the land area. With the same amount of upheaval, however, the Malay Peninsula, Sumatra, Java, and West Australia, would become united, but without extending much further seawards. Land connection, as we know, existed in Mesozoic times between Asia, Australia, and New Zealand, but the coast-lines of that distant period must have differed considerably from those that would appear were the regions in question to experience now a general elevation. The Archæan and Palæozoic rocks of the Malay Peninsula and Sumatra are flanked on the side of the Indian Ocean by great volcanic ridges, and by uplifts of Tertiary strata, which continue along the line of the Nicobar and Andaman Islands into Burma. Thus the coast-lines of that section of the Indian Ocean exhibit a geographical development similar to that of the Pacific seaboard. Elsewhere, as in Hindustan, Arabia, and East Africa, the coast-lines appear to have been determined chiefly by regional elevations of the land or subsidence of the oceanic trough in Mesozoic and Cainozoic times, accompanied by the outwelling of enormous floods of lava. Seeing, then, that the Pacific and Indian Oceans are pre-eminently regions which, down to a recent date, have been subject to great crustal movements and to excessive volcanic action, we may infer that in the development of their coast-lines the sea has played a very subordinate part. The shores, indeed, are largely protected from marine erosion by partially emerged volcanic ridges and by coral islands and reefs, and to a considerable extent also by the sediment which in tropical regions especially is swept down to the coast in great abundance by rains and rivers. Moreover, as the geological structure of these regions assures us, the land would appear seldom to have remained sufficiently long at one level to permit of much destruction by waves and tidal currents.

In fine, then, we arrive at the general conclusion that the coast-lines of the globe are of very unequal age. Those of the Atlantic were determined as far back as Palæozoic times by great mountain uplifts along the margin of the continental plateau. Since the close of that period many crustal oscillations have taken place, but no grand mountain ranges have again been ridged up on the Atlantic sea-board. Meanwhile the Palæozoic mountain-chains, as we have seen, have suffered extensive denudation, have been planed down to the sea-level, and even submerged. Subsequently converted into land, wholly or partially as the case may have been, they now present the appearance of plains and plateaus of erosion, often deeply indented by the sea. No true mountains of elevation are met with anywhere in the coast-lands of the Atlantic, while volcanic action has well-nigh ceased. In short, the Atlantic margins have reached a stage of comparative stability. The trough itself, however, is traversed by at least two well-marked banks of upheaval—the great meridional Dolphin Ridge, and the approximately transmeridional Færöe-Icelandic belt—both of them bearing volcanic islands.

But while the coast-lands of the Atlantic proper attained relative stability at an early period, those of the Mediterranean and Caribbean depressions have up to recent times been the scenes of great crustal disturbance. Gigantic mountain-chains were uplifted along their margins at so late a period as the Tertiary, and their shores still witness volcanic activity.

It is upon the margins and within the troughs of the Pacific Ocean, however, that subterranean action is now most remarkably developed. The coast-lines of that great basin are everywhere formed of grand uplifts and volcanic ranges, which, broadly speaking, are comparable in age to those of the Mediterranean and Caribbean depressions. Along the north-east margin of the Indian Ocean the coast-lines resemble those of the Pacific, being of like recent age, and similarly marked by the presence of numerous volcanoes. The northern and western shores, however (as in Hindustan, Arabia, and East Africa), have been determined rather by regional elevation or by subsidence of the ocean-floor than by axial uplifts—the chief crustal disturbances dating back to an earlier period than those of the East Indian Archipelago. It is in keeping with this greater age of the western and northern coast-lands of the Indian Ocean that volcanic action is now less strongly manifested in their vicinity.

I have spoken of the comparative stability of the earth's crust within the Atlantic area as being evidenced by the greater age of its coastal ranges and the declining importance of its volcanic phenomena. This relative stability is further shown by the fact that the Atlantic sea-board is not much disturbed by earthquakes. This, of course, is what might have been expected, for earthquakes are most characteristic of volcanic regions and of those areas in which mountain-uplifts of recent geological age occur. Hence the coast-lands of the Pacific and the East Indies, the borders of the Caribbean Sea, the volcanic ridges of the Atlantic basin, the lands of the Mediterranean, the Black Sea, and the Aralo-Caspian depressions, the shores of the Red Sea, and vast tracts of Southern Asia, are the chief earthquake regions of the globe. It may be noted, further, that shocks are not only most frequent but most intense in the neighbourhood of the sea. They appear to originate sometimes in the volcanic ridges and coastal ranges, sometimes under the floor of the sea itself. Now earthquakes, volcanoes, and uplifts are all expressions of the one great fundamental fact that the earth is a cooling and contracting body, and they indicate the lines of weakness along which the enormous pressures and strains induced by the subsidence of the crust upon its nucleus find relief. We cannot tell why the coast-lands of the Atlantic should have attained at so early a period a stage of relative stability—why no axial uplifts should have been developed along their margins since Palæozoic times. It may be that relief has been found in the wrinkling-up of the floor of the oceanic trough, and consequent formation of the Dolphin Ridge and other great submarine foldings of the crust. And it is possible that the growth of similar great ridges and wrinkles upon the bed of the Pacific may in like manner relieve the coast-lands of that vast ocean, and prevent the formation of younger uplifts along their borders.

I have already remarked that two kinds of elevatory movements of the crust are recognized by geologists—namely, axial and regional uplifts. Some, however, are beginning to doubt, with Professor Suess, whether any vast regional uplifts are possible. Yet the view that would attribute all such apparent elevations of the land to subsidence of the crust under the great oceanic troughs is not without its difficulties. Former sea-margins of very recent geological age occur in all latitudes, and if we are to explain these by sub-oceanic depression, this will compel us to admit, as Suess has remarked, a general lowering of the sea-level of upwards of 1,000 feet. But it is difficult to believe that the sea-floor could have subsided to such an extent in recent times. Suess thinks it is much more probable that the high-level beaches of tropical regions are not contemporaneous with those of higher latitudes, and that the phenomena are best explained by his hypothesis of a secular movement of the ocean —the water being, as he contends, alternately heaped up at the equator and the poles. The strand-lines in high latitudes, however, are certainly connected with glaciation in some way not yet understood. And if it cannot be confidently affirmed that they indicate regional movements of the land, the evidence, nevertheless, seems to point in that direction.

In concluding this imperfect outline-sketch of a large subject, I ought perhaps to apologize for having trespassed so much upon the domains of geology. But in doing so I have only followed the example of geologists themselves, whose divagations in territories adjoining their own are naturally not infrequent. From much that I have said, it will be gathered that with regard to the causes of many coastal changes we are still groping in the dark. It seems not unlikely, however, that as light increases we may be compelled to modify the view that all oscillations of the sea-level are due to movements of the lithosphere alone. That is a very heretical suggestion; but that a great deal can be said for it anyone will admit after a candid perusal of Suess's monumental work, "Das Antlitz der Erde."

SECTION G.

MECHANICAL SCIENCE.

OPENING ADDRESS BY W. CAWTHORNE UNWIN, F.R.S., M.INST.C.E., PRESIDENT OF THE SECTION.

BY what process selection is made of a Sectional President of the British Association is to me unknown. I may confess that it was pleasant to receive the request of the Council to preside at the meetings of Section G, even though much of the pleasure was due to its unexpectedness. I ventured to believe I might accept the honour gratefully, trusting to your kindness to assist me in fulfilling its obligations. Amongst engineers there are many with greater claims than I have to such a position, and who could speak to you from a wider practical experience. Here in Section G, I think it may be claimed that the profession of engineering owes much to some who from circumstances or natural bias have concerned themselves more with those scientific studies and experimental researches which are useful to the engineer, than with the actual carrying on of engineering operations. Here, at so short a distance from the University where Rankine and James Thomson laboured, I may venture to feel proud of being amongst those whose business it has been rather to investigate problems than to execute works.

The year just passed is not one unmemorable in the annals of engineering. By an effort remarkable for its rapidity, and as an example of organization of labour, the broad gauge system has been extinguished. It has disappeared like some prehistoric mammoth, a large-limbed organism, perfect for its purpose and created in a generous mood, but conquered in the struggle for existence by smaller but more active rivals. If we recognize that the great controversy of fifty years ago has at last been decided against Brunel, at least we ought to remember that the broad gauge system was one only of many original experiments due to his genius and courage, experiments in every field of engineering, in bridge building, in locomotive design, in ship construction, the successes and failures of which have alike enlarged the knowledge of engineers and helped the progress of engineering.

The past year has seen the completion of the magnificent scheme of water supply for Liverpool, from the Vyrnwy, carried out from 1879 to 1885 by Mr. Hawksley and Mr. Deacon, and since then completed under the direction of the latter engineer. This is one of the largest and most striking of those works of municipal engineering rendered necessary by the growth of great city communities and made possible by their wealth and public spirit. For the supply of water to Liverpool, the largest artificial lake in Europe has been created in mid-Wales, by the contruction across a mountain valley of a dam of cyclopean masonry, itself one of the most remarkable masonry works in the world. The lake contains an available supply of over 12,000 million gallons, its size having been determined not only to supply forty million gallons daily for the increasing demand of Liverpool, but also to meet the necessity imposed by Parliament that an unprecedentedly large compensation, amounting to ten million gallons daily and fifty million gallons additional on thirty-two days yearly, should be afforded to the Severn. The masonry dam, though a little less in height than some of the French dams, is of greater length. It is nearly double the length of the great dam at Verviers.[1] Athough masonry dams were an old expedient of engineers, it is in quite recent times, and chiefly in consequence of the scientific investigations of French engineers, that they have been revived in engineering practice. Since the completion of the Vyrnwy dam, another very large dam, the Tansa dam, has been completed in Bombay. This dam has a length of two miles and a height of 118 feet, and it is 100 feet thick at the base. The reservoir will supply 100 million gallons per day. In the United States a still greater work of the same kind has been commenced on the Croton river, in connection with the water supply of New York. This dam will have a length of 2000 feet, and a height of 285 feet. Its greatest thickness will be 215 feet. It will be very much the boldest work of its kind.

Returning to the Liverpool supply, the water taken from the lake at the most suitable level into a straining tower provided with very complete hydraulic machinery, passes through the Hirnant tunnel, and thence by an aqueduct, partly consisting of rock tunnels, partly of pipes 39in. to 42in. in diameter, sixty-eight miles in length, being the longest aqueduct yet constructed. The crossing of the Mersey by an aqueduct tunnel has proved the greatest engineering difficulty to be surmounted. The tunnel has been carried through layers of running sand, gravel, and silt. At first slow progress was made, but later, by the adoption of the Greathead system of shield, with air locks and air-compressing machinery, as much as fifty-seven feet of tunnel were driven and lined in one week. The whole work is now complete, and Liverpool has available an extra supply of very pure water, amounting to forty million gallons daily.

A scheme of water supply for Manchester from Lake Thirlemere in Westmoreland, on an equally large scheme, is approaching completion. Birmingham is likely to carry out another work of the same kind. And London, at a greater distance from pure water sources and under greater difficulties from the complexity of existing interests, has come to realize that, within fifty years, a population of 12½ millions will probably have to be provided for. To supply such a population, a volume of water is required ten times as great as the whole available supply from Lake Vyrnwy.

Here in Edinburgh one remembers that the birth-place of the steam-engine is near at hand. A century and a quarter ago James Watt made an invention which has profoundly influenced all the conditions of social, national, commercial, and industrial life. It is due to the steam-engine more than to any other single cause that the population in this country has tripled since the beginning of the century, and that we have become dependent on steam-power for fuel, for transport, for manufactures, in many cases for water supply, for sanitation, and for artificial light. From some German statistics it appears that there are probably now in the world, employed in industry, steam-engines exerting 49 million horse-power, besides locomotives exerting six million horse-power. Engines in steam-ships are not included. The steam-engine has become a potent factor in civilization, because it places at our disposal mechanical energy at a sufficiently low cost, and the efforts of engineers have been steadily directed to diminishing the cost at which steam-power is produced. Members of one great branch of our profession are much concerned in the production of mechanical energy at a sufficiently cheap rate. They require it in very large quantity for transformation into light and for re-transformation into mechanical energy under conditions more convenient than the direct use of steam-power. Perhaps it will not be inappropriate if in Section G I first discuss briefly some of the causes which have made the steam-engine inefficient and the extent to which we are getting to a scientific knowledge of the methods of evading them. I propose then to consider some of the methods of economizing the cost and increasing the convenience of mechanical power by generating it at central stations and distributing it, and lastly, how far means of transporting energy are likely to make available cheaper sources of energy than steam-power.

Let us go back for a moment to James Watt. The most distinct feature about the invention of the steam-engine is that it arose out of studies of such questions as the relation of pressure and temperature of steam, the heat absorbed in producing it, and its volume at different pressures.

Armed with this knowledge, Watt was able to determine that the quantity of steam used in a model atmospheric engine was enormously greater than that due to the volume described by the piston. There was waste or loss. To discover the loss was to get on the path of finding a remedy. The separate condenser, by diminishing cylinder condensation, annulled a great part of the loss. So great was Watt's insight into the action of the engine that he was able to leave it so perfect that, except in one respect, little remained for succeeding engine builders, except to perfect the machines for its manufacture, to improve its details, and to adapt it to new purposes. Now it very early became clear that there were two directions of advance which ought to secure greater economy. Simple mechanical indications showed that increased expansion ought to ensure increased economy. Thermodynamic considerations indicated that higher pressures, involving a greater temperature range of working, ought to secure greater economy. But in attempting to advance in either of these directions, engineers were more or less disappointed. Some of Watt's engines worked with 5 lbs. of coal per indicated horse-power per hour. Many engines with greater pressures and longer expansions have done but little better. The history of steam-engine improvement for a quarter of a century has been an attempt to secure the advantages of high pressures and high ratios of expansion. The difficulty to be overcome has proved to be due to the same cause as the inefficiency of Watt's model engine. The separate condenser diminished, but it did not annul, the action of the cylinder wall. The first experiments which really startled thoughtful steam engineers were those made by Mr. Isherwood, between 1860 and 1865. Mr. Isherwood showed that in engines such as those then in use in the United States Navy, with the large cylinders and low speeds then prevalent, any expansion of the steam beyond three times led, not to an increased economy, but to an increased consumption of steam. Very little later than this M. Hirn undertook, in 1871–5, his classical researches on the action of the steam in an engine of about 150 indicated horse-power. Experiments of greater accuracy or completeness, or of greater insight into the conditions which were important, have never since been made, and Hirn with his assistants, MM. Hallaner and Dwelshauvers Dery, has determined, once for all, the whole method of a perfect steam-engine trial. M. Hirn was the first to clearly realize that the indicator gives the means of determining the steam present in the cylinder during every period of the cycle of the engine. Consequently, superheating in ordinary cases being out of the question, we have the means of determining the heat present and the heat already converted into work. The heat delivered into the engine is known from boiler measurements, combined with calorimetric tests of the quality of the steam, tests which Hirn was the first to undertake. The balance or heat unaccounted for is, then, a waste or loss due to causes which have to be investigated. Hirn originated a complete method of analysis of an engine test, showing at every stage of the operation the heat accounted for and a balance of heat unaccounted for; and the latter proved to be a very considerable quantity.

---

[1] The length of the dam from rock to rock is 1172 feet. Height from lowest part of foundation to parapet of carriage way, 161 feet. Height from bed of river to overflow sill, 84 feet. Thickness of masonry at base, 120 feet.

Meanwhile theoretical writers, especially Rankine and Clausius, had been perfecting a thermodynamic theory of the steam-engine, based primarily on the remarkable and irrefragable principle of Carnot. The result of Hirn's analysis was to show that these theories, applied to the actual steam-engine, were liable to lead to errors of 50 or 60 per cent., the single false assumption made being that the interaction between the walls of the cylinder and the steam was an action small enough to be negligeable.

In this country Mr. Mair Rumley, following Hirn's method, made a series of experiments on actual engines with great care and accuracy and completeness. All these experiments demonstrated the fact of a large initial condensation of steam on the walls of the cylinder, alike in jacketed and unjacketed engines. This condensed steam is re-evaporated partially during expansion, but mainly during exhaust, and serves as a mere carrier of heat from boiler to condenser, in conditions not permitting its utilization in producing work.

It became clear from Hirn's experiments, if not from the earlier experiments of Isherwood, that for each engine there is a particular ratio of expansion for which the steam expenditure per horse-power is least. Professor Dery has since deduced from them that the practical condition of securing the greatest efficiency is that the steam at release should be nearly dry. In producing that dryness the jacket has an important influence. In spite of much controversy amongst practical engineers about the use of the jacket, it does not appear that any trustworthy experiment has yet been adduced in which there was an actual loss of efficiency due to the jacket. In the older type of comparatively slow engines it is a rule that the greater the jacket condensation the greater the economy of steam, even when the jacket condensation approaches 20 per cent. of all the steam used. It appears, however, that as the speed of the engine increases, the influence of the jacket diminishes, so that for any engine there is a limit of speed at which the value of the jacket becomes insignificant.

Among steam-engine experiments directed specially to determine the action of the cylinder walls, those of the late Mr. Willans should be specially mentioned. Mr. Willans' death is to be deplored as a serious loss to the engineering profession. His steam-engine experiments, some of them not yet published, are models of what careful experiments should be. They are graduated experiments designed to indicate the effect of changes in each of the practically variable conditions of working. They showed a much greater variation of steam consumption (from 46 to 18 lbs. per indicated horse-power hour) in different conditions of working than, I think, most practical engineers suspected, and this has been made more significant in later experiments, on engines working with less than full load. The first series showed that in full load trials the compound was superior to the simple engine in practically all the conditions tried, but that the triple was superior to the compound only when certain limits of pressure and speed were passed.

As early as 1878 Prof. Cotterill had shown that the action of a cylinder wall was essentially equivalent to that of a very thin metallic plate, following the temperature of the steam. The exceedingly rapid dissipation of heat from the surface during exhaust especially being due to the evaporation of a film of water initially condensed on its surface. In permanent *régime* the heat received in admission must be equal to that lost after cut off. In certain conditions it appeared that a tendency would arise to accumulate water on the cylinder surfaces, with the effect of increasing in certain cases the energy of heat dissipation. Recently Prof. Cotterill has been able to carry much further the analysis of the complex action of condensation and re-evaporation in the cylinder, and to discriminate in some degree between the action of the metal and the more ambiguous action of the water film. By discarding the less important actions, Prof. Cotterill has found it possible to state a semi-empirical formula for cylinder condensation in certain restricted cases which very closely agrees with experiments on a wide variety of engines. It is to be hoped that, with the data now accumulating, a considerable practical advance may be made in the clearing up of this complex subject. There are, no doubt, some people who are in the habit of depreciating quantitative investigations of this kind. They are as wise as if they recommended a manufacturer to carry on his business without attending to his account books. Further, the attempt to obtain any clear guidance from experiments on steam-engines has proved a hopeless failure without help from the most careful scientific analysis. There is not a fundamental practical question about the thermal action of the steam-engine, neither the action of jackets or of expansion or of multiple cylinders, as to which contradictory results have not been arrived at, by persons attempting to deduce results from the mass of engine tests without any clear scientific knowledge of the conditions which have affected particular results. In complex questions fundamental principles are essential in disentangling the results. Interpreted by what is already known of thermodynamic actions, there are very few trustworthy engine tests which do not fall into a perfectly intelligible order. There is only one known method, not now much used, by which the cylinder condensation can be directly combated. Thirty years ago superheating the steam was adopted with very considerable increase of economy. It is likely that it was thought by the inventor of superheating that an advantage would be gained by increasing the temperature range. If so, his theory was probably a mistaken one. For the cooling action of the cylinder is so great that the steam is reduced to saturation temperature before it has time to do work; but the economy due to superheating was unquestionable, and was very remarkable considering how small a quantity of heat is involved in superheating. The heat appears to diminish the cylinder wall action so much as almost to render a jacket unnecessary. The plan of superheating was abandoned from purely practical objections, the superheaters then constructed being dangerous. Recently superheating has been tried again at Mulhouse by M. Meunier, and his experiments are interesting because they are at higher pressures than in the older trials and with a compound engine. It appears that even when the superheater was heated by a separate fire there was an economy of steam of 25 to 30 per cent. and an economy of fuel of 20 to 25 per cent., and four boilers with superheating were as efficient as five without it.

It may be pointed out as a point of some practical importance that if a trustworthy method of superheating could be found, the advantage of the triple over the compound engine would be much diminished. For marine purposes the triple engine is perfectly adapted. But for other purposes it is more costly than the compound engine, and it is less easily arranged to work efficiently with a varying load.

There does not seem much prospect of exceeding the efficiency attained already in the best engines, though but few engines are really as efficient as they might be, and there are still plenty of engines so designed that they are exceedingly uneconomical. The very best engines use only from 12 to 13 lbs. of steam per indicated horse-power hour, having an absolute efficiency reckoned on the indicated power of 16 per cent., or reckoned on the effective power, 13 per cent. The efficiency, including the loss in the boiler, is only about 9 per cent. But there are internal furnace engines of the gas-engine or oil-engine type in which the thermal efficiency is double this.

In his interesting address to this Section in 1878, Mr. Easton expressed the opinion that the question of water-power was one deserving more consideration than it had lately received, and he pointed to the variation of volume of flow of streams as the principal objection to their larger utilization. Since that time the progress made in systems of transporting and distributing power has given quite a new importance to the question of the utilization of water-power. There seems to be a probability that in many localities water-power will, before long, be used on a quite unprecedented scale, and under conditions involving so great convenience and economy that it may involve a quite sensible movement of manufacturers towards districts where water-power is available.

If we go back to a period not very distant in the history of the world, to the middle of the last century, we reach the time when textile manufactures began to pass from the condition of purely domestic industries to that of a factory system. The fly-shuttle was introduced in 1750, the spinning-jenny was invented in 1767, and Crompton's machine only began to be generally used in 1787. It was soon found that the new machines were most suitably driven by a rotary motion, and after some attempts to drive them by horses, water-power was generally resorted to. In an interesting pamphlet on the Rise of the Cotton Trade, by John Kennedy, of Ardwick Hall, written in 1815, it is pointed out that the necessity of locating the mills where water-power was available, had the disadvantages of taking them away from the places where skilled workmen were found, and from the markets for the manufactured goods. Nevertheless, Mr. Kennedy states that for some time after Arkwright's first mill was built at Cromford, all the principal mills were erected near river falls, no other power than water-power having been found practically useful. "About 1790," says Mr. Kennedy, "Mr. Watt's steam-engine began to be understood, and waterfalls became of less value. Instead of carrying the workpeople to the power, it was found preferable to place the power amongst the people."

The whole tendency of the conditions created by the use of steam-power has been to concentrate the industrial population in large communities, and to restrict manufacturing operations to large factories. Economy in the production of power, economy in superintendence, the convenience of the subdivision of labour, and the costliness of the machines employed, all favoured the growth of large factories. The whole social conditions of manufacturing centres have been profoundly influenced by these two conditions—that coal for raising steam can be easily brought to any place where it is wanted, and that steam-power is more cheaply produced on a large scale than on a small scale. It looks rather, just now, as if facilities for distributing power will to some extent reverse this tendency.

Let me first point out that water-power, where it is available, is so much cheaper and more convenient than steam-power that it has never been quite vanquished by steam-power.

I find, from a report by Mr. Weissenbach, that in 1876 70,000 horse-power derived from waterfalls were used in manufacturing in Switzerland. According to a census in 1880, it appears that the total steam and water-power employed in manufacturing operations in the United States was 3,400,000 horse-power. Of this, 2,185,000 horse-power, or 64 per cent., was derived from steam, and 1,225,000 horse-power, or 36 per cent., from water. In the manufacture of cotton and woollen goods, of paper and of flour, 760,000 horse-power were obtained from water, and 515,000 horse-power from steam. If statistics could be obtained from other countries, I believe it would be found that a very large amount of water-power is actually made available. The firm of Escher Wyss and Company, of Zurich, have constructed more than 1800 turbines of an aggregate power of 111,460 horse-power.

With a very limited exception all the water-power at present used is employed in the neighbourhood of the fall where it is generated. If means were available for transporting the power from the site of the fall to localities more convenient for manufactures, there can be no doubt that a much larger amount of water-power would be used, and the relative importance of water and steam power in some countries would probably be reversed. It is because recent developments seem to make such a transport of power possible without excessive cost and without excessive loss, that a most remarkable interest has been excited in the question of the utilization of water-power. Take the case of Switzerland for instance. At the present time Switzerland is said to pay to other countries £800,000 annually for coal. But the total available water-power of Switzerland is estimated at no less than 582,000 horse-power, of which probably only 80,000 are at present utilized. I found a year ago that nearly every large industrial concern in Switzerland was preparing to make use of water-power, transported a greater or less distance. Besides the great schemes actually carried out at Schaffhausen, Bellegarde, Geneva, and Zurich, where water-power is already utilized on a very large scale, there is a project to develop 10,000 horse-power on the Dranse near Martigny.

Hence it is easy to see that problems of distribution of power—that is, the transformation of energy into forms easily transportable and easily utilizable—have now a great interest for engineers.

Besides the power required for manufacturing operations, there is a steadily increasing demand for easily available mechanical energy in large towns. For tramways, for lifts, for handling goods, for small industries, for electric lighting, and sometimes for sanitation, power is required. Hitherto steam-engines, or more lately gas-engines, have been used, placed near the work to be done. But this sporadic generation of power is uneconomical and costly, especially when the work is intermittent; the cost of superintendence is large, and the risk of accident considerable. Hence attention is being directed to systems in which the mechanical energy of fuel or falling water is first generated in large central stations, transformed into some form in which it is conveniently transportable and capable of being rendered available by simpler motors than steam-engines.

Just as in great towns it has become necessary to supersede private means of water supply by a municipal supply; just as it has proved convenient to distribute coal-gas for lighting and heating, and to provide a common system of sewerage, so it will probably be found convenient to have in all large towns some means of obtaining mechanical power in any desired quantity at a price proportionate to the quantity used, and in a form in which it can be rendered available, either directly or by simple motors requiring but little skilled superintendence.

Telodynamic Transmission.—First, then, let me say a few words as to the modes of distributing power which it is possible to adopt. In 1850, at Logelbach in Alsace, M. Ferdinand Hirn used a flat steel belt to transmit power directly a distance of eighty metres. Subsequently a wire rope was used on grooved pulleys. This worked so well that a second transmission to a distance of 240 metres was erected. The details of the system were worked out with great care with a view to securing the least cost of construction, the least waste of energy, and the greatest durability of the ropes. So successful did this system of telodynamic transmission prove that within ten years M. Martin Stein, of Mulhouse, had erected 400 transmissions, conveying 4200 horse-power, and covering a distance of 72,000 metres.

Just at this time a very able and far-seeing manufacturer at Schaffhausen, Herr Moser, had formed a project for reviving the failing industries of the town by utilizing part of the water-power of the Rhine: Hirn's system of wire-rope transmission rendered this project practicable. The works were commenced in 1863. Three turbines of 750 horse-power were erected on a fall which varies from 12 to 16 feet, created by a weir across the river. From the turbines the power is transmitted by two cables, in one span of 392 feet, across the river. Similar cables distribute the power to factories along the river bank. In 1870 the transmission extended to a distance of 3400 feet. Power is sold at rates varying from £5 to £6 per horse-power per annum. In 1887 there were twenty-three consumers of power paying a rental of £3500 per annum for power. The project has been financially successful, and is still working. At Zurich, Freiberg, and Bellegarde there are similar installations, and a large scheme of the same kind has recently been carried out at Gokak in India. Wire-rope transmissions are of great mechanical simplicity, and the loss of power in transmission is exceedingly small. They are extremely suitable for certain cases where a moderate amount of power has to be transmitted a moderate distance, to one or to a few factories. On the other hand, they become cumbrous if the amount of power transmitted exceeds 600 or 1000 horse-power. The wear of the ropes, which only last a year, has proved greater than was expected, and is a source of considerable expense.

The practical introduction of a system of distributing power by *pressure water* is due to Lord Armstrong. Such a system involves a central pumping station, a series of distributing mains, and suitable working motors. From its first introduction the peculiar advantages of this system for driving intermittently working machines, such as lifts, dock machinery, railway cranes, and hauling gear, became obvious. But, with intermittent working machines, there rose the need of an appliance for storing energy during periods of minimum demand and restoring it in periods of maximum demand. The invention of the accumulator by Lord Armstrong made the system of hydraulic transmission a success, and at the same time fixed its character as a system specially adapted for those cases where intermittent work is required to be done. Lord Armstrong's system of hydraulic distribution by water at a pressure of 700 or 800 lbs. per square inch, with the use of accumulators for equalizing the variations of supply and demand, has now been widely adopted. The most extensive scheme of that kind hitherto executed is the important scheme carried out by the Hydraulic Power Company. Over fifty miles of pressure mains have now been laid in the streets of London. The Falcon Wharf pumping station contains four sets of compound pumping engines, each of 200 horse-power. Two additional pumping stations have now been erected, and 1500 lifts are worked from the pressure mains. The minimum charge for water is 2*s.* per 1000 gallons. This rate of charge is economical for such machines as lifts, but it would be extravagant for machines working continuously. It would be equivalent to a charge of nearly £50 per horse-power per year of 3000 working hours, apart from interest and maintenance of machines.

I shall indicate later on that in some cases where local conditions are favourable, where there is cheap water-power, and the possibility of constructing high-level storage reservoirs, then hydraulic transmission can be adopted with success for distributing power for ordinary manufacturing purposes. But neither telodynamic transmission nor hydraulic transmission have proved suitable as methods for the general distribution of motive power from central stations. Distribution by steam and distribution by heated water have both been tried in the United States, but not with very remarkable success. Only two other methods are available—distribution by compressed air and distribution by electricity.

For many years *compressed air* has been used to distribute power in tunnelling and mining operations to considerable distances. It is only recently that it has been used as a general method of distributing power to many consumers. In many installations the machinery has been rough and unscientific, and the waste of energy very considerable. It is through experience gained and improvements carried out in the remarkable system now at work in Paris, and known as the Popp system, that the great advantages of compressed air distribution have been proved. The Paris system has very gradually developed. About 1870 a small compressing station was erected to actuate public and private clocks by intermittent pulses of air conveyed along pipes chiefly laid in the sewers. In 1889 about 8000 clocks were thus driven. Meanwhile the compressed air had also been applied to drive motors for small industries. The demand for power thus supplied grew so rapidly that a second compressing station was built in the Rue de Saint Fargeau. In 1889 steam air compressors of 2000 horse-power were at work, and additional compressors were under construction. The pressure at that time was five atmospheres, and the largest air mains were 12 inches in diameter. Ingenious and simple rotary machines were used as air motors for small powers, and for larger powers any ordinary steam-engine was converted into an air motor. Prof. Kennedy made tests in 1889, which were communicated to this Association. He found that a motor four miles from the compressing station indicated 10 horse-power for 20 indicated horse power expended at the compressing station, an efficiency of 50 per cent. only. There were then 225 motors worked from the air mains.

Since 1889 more extended investigations have been made by Professor Riedler, of Berlin, and the chief part of the waste of work has been traced to inefficiency of the air compressors. Compound air compressors of much higher efficiency have now been constructed. The plant at the Saint Fargeau station has been increased to 4000 horse-power. A new station has been erected on the Quai de la Gare, intended ultimately to contain compressors of 24,000 horse-power. Compressors of 10,000 horse-power are already under construction.

Compressed air transmission, whether or not it is the most economical system, is undoubtedly applicable for the distribution of power on a very large scale and to very considerable distances. There is nothing in any of the appliances which is novel or imperfectly understood. The air is used in the consumer's premises in machinery of well-understood types, and old steam engines can be converted into air motors without difficulty and without alteration of existing transmissive machinery in the factories. Not least important, the air can be measured with accuracy enough for practical purposes by simple meters, and charged for in proportion to the power consumed. Air compressors and air motors are not as efficient as dynamos and electric motors, but in one respect distribution by air and electricity are similar. For distances which are not more than a few miles the loss of energy in transmission is small enough to be insignificant.

There is yet one other mode of power distribution which promises to become the most important of all, and which, in the case of transmission to very great distances, if such transmission becomes necessary, has undoubtedly great advantages over every other method.

About *electrical distribution* of power I shall not venture to say much, partly because I am not an electrical expert, partly because it has been lately pretty fully discussed. In the United States there has been an enormous development of electric tramways, which are essentially cases of electric power distribution. In this country we have the South London and some other railways worked electrically. There are others also on the Continent. But electrical power distribution to private consumers for industrial purposes has not yet made as much progress as might have been expected. Perhaps electrical engineers have been so busy with problems of electric lighting that they have had no time to settle the corresponding problems of power distribution.

No doubt continuous current distribution presents at the moment the fewest difficulties, or, at any rate, involves the fewest comparatively untried expedients. Several continuous-current plants for distributing power are in operation, of which perhaps the most interesting is that at Oyonaz, which was described in Section G last year by Prof. G. Forbes. There 300 horse-power obtained by turbines is transmitted 8 kilometres at 1800 volts. It is then let down by motor transformers to a voltage suitable for lighting and driving motors. A number of small workshops are driven, the power being supplied at a fixed rent.

At the Calumet and Hecla mines on Lake Superior, at the Dalmatia mines in California, and some other places, energy derived from turbines is transmitted distances of a mile or two by continuous electric currents and used in driving mining machinery, and some cases of the use of electrical distribution in mines in this country were mentioned by my predecessor in his address last year.

At Bradford a few electric motors are being worked from the electric lighting mains. The largest of these is of twenty horse-power. The price at which the electricity is supplied is not given, but I believe the cost is high when reckoned for continuous working. It would seem that it must be so when the electric current is generated by steam power.

At Schaffhausen an electric transmission has now been constructed alongside of the wire-rope transmission. The power is derived from two turbines, and is transmitted across the Rhine, a distance of 750 yards, at 624 volts. The current drives a spinning-mill, in which the largest motor is 380 horse-power. The power is sold, I believe, at £3 per horse-power of the motors per annum.

Many engineers have now apparently come to the conclusion that alternating currents will be better for power transmission to considerable distances than continuous currents. One interesting alternate current transmission, partly for power, partly for lighting purposes, has been for some time in operation at Genoa.

On the line of the aqueduct bringing water from the Gorzente rivulet three electric stations are being established. The reservoirs are 2050 feet above Genoa, and as this is a much greater fall than is required for water-supply purposes, part can be used to generate about 1600 horse-power.

In the first of the power stations erected there are turbines of 450 horse-power driving two dynamos. A second larger station was completed in November. In this there are eight alternate-current dynamos of 70 horse-power each. Six alternators are worked in series, transmitting a current of 6000 volts. The current is transmitted sixteen miles by bare copper wires, 8·5 mm. diameter, placed overhead. The current is used both for lighting and power purposes.

Another method of using alternating currents was adopted in the remarkable experiment at Frankfort last year. In that case energy obtained by turbines at Lauffen was transmitted to

Frankfort, a distance of 108 miles, and used for lighting and driving a motor. The current was obtained at low tension, transformed up to a tension of 18,000 to 27,000 volts for transmission, and then transformed down again for distribution. The loss in the conducting wires ranged from 5 horse-power when the turbines worked at 100 horse-power, to 25 horse-power when the turbines worked at 200 horse-power. The efficiency of dynamo, two transformers, and line ranged from 68 to 75 per cent., a remarkably satisfactory result.

There can be little doubt that if efficient and durable transformers can be constructed, they do give a considerable advantage to an alternate-current system. To an ordinary engineer it appears also that the system of producing current at a low tension in the dynamo, and using it at low tension in the motors, permits the construction of dynamos and motors more mechanically unexceptionable than those worked at high voltage.

I have spoken of the growth of a demand for power distributed in a convenient form in towns. The power distribution in London, Manchester, Birmingham, and Liverpool by pressure water, and that by compressed air in Paris, shows how rapidly, when power is available, a demand for it arises. A striking instance may be found in the small town of Geneva.

In 1871, soon after the completion of the earlier system of low-pressure water supply, Col. Turrettini applied to the municipal council to place a pressure engine on the town mains for driving the factory of the Society for Manufacturing Physical Instruments. The plan proved so convenient that nine years after, in 1880, there were in Geneva 111 water-motors supplied from the low-pressure mains, using 34,000,000 cubic feet of water annually, and paying to the municipality nearly £2000 a year. The cost of the power was not low. It was charged at a rate equivalent to from £36 to £48 per horse-power per year of 3000 working hours. But even the high price did not prevent the use of power so conveniently obtainable.

Since then a high-pressure water service has been established, the water being pumped by turbines in the Rhone. From this high-pressure service power is supplied more cheaply. On the high-pressure system the cost of the power is about 0·7*d.* per horse-power hour, or £8 per horse-power for 3000 working hours.

In 1889 the annual income from water sold for power purposes on the low-pressure system was £2085 and on the high-pressure system £4500. On the high-pressure system the receipts in 1889 were increasing at the rate of £880 per year.

In 1889 the motive power distributed, on the high-pressure system alone, amounted to 1,500,000 horse-power hours, there being seventy-nine motors of an aggregate working power of 1279 horses.

In Zurich there is quite a similar system and power, amounting to 9,000,000 horse-power hours in the year, distributed hydraulically to various consumers, who pay a rental of £1200 per annum. It will be noted that all this power in Geneva and Zurich is obtained from water which has been pumped, and it is the low cost of the water-power which does the pumping which makes this possible.

But, further, in both Geneva and Zurich the whole of the dynamos supplying electric light are also driven by turbines using pumped water. The convenience of this arises in this way. The fall obtainable in the river in both cases is a small one, and varies. Large turbines are required, and these cannot work at a constant speed. Further, it is expensive to use these large low-pressure turbines to drive directly dynamos which only work with a considerable load for a short portion of the day. The low-pressure turbines in the river are therefore used to pump water to a high-level reservoir, and they work with a constant load all the twenty-four hours.

From the high-level reservoir water is taken as power is required to drive the dynamos, and the turbines driving the dynamos are small high-pressure turbines, working always on a constant fall at a regular speed, and easily adjusted by a governor to a varying load. The system seems a roundabout one, but it is perfectly rational, effective, and economical.

Few persons can have seen Niagara Falls without reflecting on the enormous energy which is there continuously expended, and for any useful purpose wasted. The exceptional constancy of the volume of flow, the invariability of the levels, the depth of the plunge over the escarpment, the solid character of the rocks, all mark Niagara as an ideally perfect water-power station; while, on the other hand, the remarkable facilities of transport, both by steam navigation on the lakes and by four systems of railway, afford commercial advantages of the highest importance. From a catchment basin of 240,000 square miles, an area greater than that of France, a volume of water amounting to 265,000 cubic feet per second descends from Lake Erie to Lake Ontario, a vertical distance of 326 feet, in 37½ miles.

Supposing the whole stream could be utilized, it would supply 7,000,000 horse-power. This is more than double the total steam and water-power at present employed in manufacturing industry in the United States.

Immediately below the Falls the river bends at right angles, and flows through a narrow gorge. The town of Niagara Falls on the American side occupies the table-land in this angle.

The earliest traders who settled near the Falls erected stream mills in the Upper River in 1725 for preparing timber. Later, the Porter family erected factories on the islands in the rapids above the falls. It was not, however, till about thirty years ago that any systematic attempt was made to utilize part of the water-power of the Falls. Then a canal was constructed from Port Day, about three-quarters of a mile above the Falls, to a fore-bay or head-race along the cliff overlooking the lower river. In 1874 the Cataract Mill was established, taking power from this canal, and other mills were gradually erected till about 6000 horse-power were utilized. These mills have been exceedingly prosperous, but since the growth of a feeling against the disfigurement of the Falls it has become impossible to extend works of the same kind.

The idea of a method of utilizing the Falls, capable of greater development, and free from the objections to the hydraulic canal with mills discharging tail water on the face of the cliff, is due to the late Mr. Thomas Evershed, Division Engineer of the New York State Canals. He proposed to construct head-race canals on unoccupied land some two miles above the Falls. From these the water was to fall through vertical turbine pits into tail-race tunnels, converging into a great main tunnel, discharging into the lower river. Apart from an inappreciable diminution in the volume of flow over the Falls, this plan avoids any disfigurement of the scenery near the Falls, and permits a head of nearly 200 feet to be made available. It is, however, essential to such a plan that work should be undertaken on a very large scale. In 1886 the Niagara Falls Company was incorporated, and obtained options over a considerable area of land, extending from Port Day for two miles along the Niagara River. In 1889 the Cataract Construction Company was formed to mature and carry out the constructional works required.

The present plans contemplate the utilization of 100,000 effective horse-power. The principal work of construction is a great tunnel 7260 feet long, which is to form a tail-race to the turbines, starting from lands belonging to the Company, and discharging into the lower river. The tunnel is 19 feet by 21 feet, or 386 square feet in area, inside a brickwork lining 16 inches thick.

The base of the tunnel is 205 feet below the sill of the head gate, and permits a fall of 140 to be rendered available at the turbines. The brickwork of the tunnel is lined for 200 feet from the mouth with cast-iron plates.

The tunnel has been excavated with remarkable rapidity with the aid of drills worked by compressed air.

The main head-race, about 200 feet wide, will run for about 5000 feet parallel with the river, having entrances from the river at both ends. Near the lower reach the Soo Paper Company is already arranging to utilize 6000 horse-power, discharging the water from the turbines through a lateral tunnel into the main tunnel. Near this lower reach will also be placed two principal power stations, from which power will be distributed, either electrically or otherwise in ways not yet fully determined. The first turbines to be erected in these power stations will be twin turbines of the outward flow type of 5000 effective horse-power. These turbines have a vertical shaft for driving dynamos or other machinery placed above ground.

According to Mr. Evershed's original plans, it was intended to distribute water by surface canals to different power users, each of whom would sink his own turbine pits, connected below by lateral tunnels to the main discharge tunnel. Some of the power at Niagara will undoubtedly be used in this way, and in the case of industries requiring a large amount of power it will be economical to purchase a site and water rights.

Such a plan is, however, not adapted to smaller factories. Obviously for them it would be more economical to develop the power in one or more central stations by turbines of large size under common management. Further, once given the means of distributing power instead of water, an important extension of the project becomes possible.

Besides supplying power to industries which may locate themselves at Niagara, the power may be transmitted to the existing factories in Buffalo and Tonawanda.

Arrangements are already proceeding to transmit 3000 horse-power to Buffalo, a distance of 18 miles, to work an electric lighting station.

In 1890, Mr. Adams, the President of the Niagara Construction Company, visited Europe to examine systems of power distribution. It was in consequence of this visit that the important modification of the plans of the Company involved in the substitution, to a large extent, of a system of power distribution, for a system of water distribution came to be adopted. The American engineers were anxious to obtain the best European advice as to the methods best suited to the local conditions. A commission was formed, consisting of Lord Kelvin, Dr. Coleman Sellers, Prof. Mascart, and Colonel Turrettini, and an invitation was given to engineers and engineering firms in Europe and America to send in competitive projects for the utilization of the power at Niagara and its distribution to different consumers at Niagara and in Buffalo by electrical or other means. Many of the plans sent in were worked out with great care and completeness. As to the hydraulic part of the projects there was some approach to general consent as to the arrangements to be adopted, but as to the methods of distributing the power there was an extraordinary diversity.

Generally the Commission reported in favour of electrical distribution, with perhaps a partial use of compressed air as an auxiliary method.

Generally also they reported in favour of methods of distribution by continuous currents in preference to alternating currents. Since the date at which the Commission reported, the Frankfort-Lauffen experiment has been made, and in the opinion of some electrical engineers a distinct advance has been achieved in the use of alternating currents at high potential.

The Company has not yet decided to adopt any plan for the central stations except in a tentative way. One or more turbines of 5,000 horse-power are to be erected, and probably at first this power will be distributed to Buffalo by an alternating current system.

The cost of a steam horse-power at Buffalo is reckoned at 35 dollars per annum. I believe the Company will be able to deliver power at from 10 dollars for large amounts, and a greater price for small amounts, this price being reckoned for twenty-four hour days.

The new industry of electric lighting has made necessary the provision of large amounts of motive power. Electric traction similarly depends on the supply of motive power. New chemical and metallurgical processes are being introduced which entirely depend for their commercial success on the supply of motive power at a low price.

Niagara is likely to become not only a seat of large manufacturing operations of familiar types, but also the home of important new industries.

NOTES.

WE regret to have to announce the death of Sir Daniel Wilson, the President of Toronto University.

ALTHOUGH the sixth International Geographical Congress will not assemble in London until June, 1895, arrangements are already being made in connection with it. The organizing committee is not quite completed, and the Royal Geographical Society is still adding to it. Among those already nominated are the President of the Society (Sir Mountstuart Grant Duff), the honorary Secretaries of the Society (Messrs. Douglas Freshfield and Henry Seebohm), Sir George Bowen, Sir Charles Wilson, General J. T. Walker, Major Darwin, M.P., Mr. J. Scott Keltie, Sir Frederick Abel, Sir Henry Barkley, and General J. F. D. Donnelly. This committee is busily engaged in making its arrangements.

THERE has been a recrudescence in the eruption of Etna during the past week. We trust that there is a local successor to the lamented Prof. Silvestri to give us some day a complete history of the phenomena.

THE weather during the past week has been very unsettled, although during the first part the disturbances were mostly confined to the north. The anticyclone which had for some time lain to the westward of our islands moved southwards, and shallow depressions appeared off Scotland. The prevailing winds were consequently westerly or south-westerly, and temperature was rather above the average, except in the north and west, where the daily maxima were frequently below 60°, being some degrees lower than the average. On Sunday a rather deep depression from the Atlantic became central over our islands, accompanied by very heavy rainfall in Ireland and Wales, and rainy weather subsequently spread over the whole of the kingdom; while a considerable fall of temperature and strong northerly winds followed the passage of the depression to the eastwards. The report issued by the Meteorological Council for the week ending the 6th instant shows that the rainfall only exceeded the mean in the north of Scotland; in all other districts there was a deficit. The deficiency was greatest in the south-west of England, where it amounted to eight inches since the beginning of the year.

PROF. LOEFFLER, of the University, Greifswald, has published two articles in the *Centralblatt für Bakteriologie*, on his discovery of, and experiments with, the *Bacillus typhi murium*, and on the result of its application, at the request of the Greek Government, to arrest a plague of field-mice in Thessaly. In view of their scientific interest, these articles have been translated under the direction of Mr. Harting, and will appear in the next number of *The Zoologist*.

VON HELLMUTH PANCKOW contributes an article on the dwarf races in Africa and South India to the recent number of the *Zeitschrift der Gesellschaft für Erdkunde*.

A MOST important report of the sugar-cane borers, which do so much harm in the West Indies, from the pen of Mr. W. F. H. Blandford (Lecturer on Entomology, Cooper's Hill), appears in the *Kew Bulletin* for July and August.

THE *Monthly Weather Review*, of the Dominion of Canada, for April 1892 contains notices of aurora seen on almost every day of the month. The most widely-observed display occurred on the 23rd, 24th, and 25th.

THE *Abhandlungen* of the Royal Prussian Meteorological Institute (Bd. I., No. 5) contains a very elaborate investigation, 154 quarto pages, of the aspiration apparatus invented by Dr. R. Assmann, of Berlin, an instrument intended to determine the true temperature and humidity of the air under any conditions. The first apparatus of this kind was invented by Mr. John Welsh in 1853, and was used by him and also by Mr. Glaisher in their balloon ascents, after which time it appears to have been overlooked, or set aside, until it was again reinvented by Dr. Assmann, in a modified form, in 1889. We cannot enter into the construction of the apparatus here, further than stating that by the rotation of discs, the continual renewal of the air in connection with very sensitive thermometers is ensured, by which means sudden changes of temperature which cannot be followed by an ordinary thermometer are indicated. The apparatus is used at the Prussian Institute and at the German colonies in Africa as a standard instrument for the determination of the true temperature and humidity of the air. For ordinary stations however, or for observations at sea, we presume that it is not likely to come into general use.

THE report of the director of the Hong Kong Observatory for the year 1891 contains a table of the monthly and yearly rainfal value for about forty years. The mean yearly value is

90·17 inches, most of which falls between May and September. Dr. Doberck states that there is apparently a little more rain when there are many spots on the sun, but the difference is too slight to be of any practical importance. The east wind is most prevalent at all seasons, the colony being within the region of the trade wind; about 59 per cent. of all winds blow from this quarter, but from June till September there is also a southerly maximum, caused by the monsoon. In winter the temperature is highest with south, and lowest with north wind, and in summer it is highest with south-west, and lowest with east winds. During the year, 213 ships' log-books have been examined for data relating to typhoons, and registers have been regularly kept at about forty stations.

THE additions to the Zoological Society's Gardens during the past week include two Macaque Monkeys (*Macacus cynomolgus*, ♂ ♂) from India, presented respectively by Lieutenant H. S. Wilson and Mrs. Dunnington Jefferson; a Ring-tailed Coati (*Nasua rufa*) from South America, presented by Mr. C. Carrington; an Angolan Vulture (*Gypohierax angolensis*, juv.), a —— Buzzard (*Buteo* ——) from West Africa, presented by Dr. Ferrier; a Spiny-tailed Mastigure (*Uromastix acanthinurus*) from Algeria, presented by Lady Sebright; a Black-headed Caique (*Caica melanocephala*) from Demerara, two Spiny-tailed Mastigures (*Uromastix acanthinurus*) from Algeria, deposited; three Short-headed Phalangers (*Belidens breviceps*) from Australia, a Hairy Armadillo (*Dasypus villosus*, ♂) from La Plata, a White-throated Capuchin (*Celeus hypoleucus*, ♀) from Central America, four Scarlet Ibises (*Eudocimus ruber*) from Para, purchased; a Testaceous Snake (*Ptyas testacea*) froms California, received in exchange.

OUR ASTRONOMICAL COLUMN.

NATAL OBSERVATORY.—The superintendent of the Nata Observatory, in his report for the year 1890–91, tenders hi obligations to no less than seven ladies, without whose zealou assistance, he says, the greater part of the numerous astronomica computations, &c., would not have been carried out. Although lacking such aid as is consistent with the proper working of an Observatory, a great amount of very useful work has been accomplished. For instance, the entire mass of meridian observations of the moon made at Greenwich during the period 1851–1861 have been reduced and compared with the theoretical basis of Hansen's Lunar Tables, thus completing the whole number of lunar observations up to the year 1890. The work with the transit, magnetic transit, and equatorial have been continued as usual. For the determination of the latitude of the Observatory 1022 observations of thirty-five pairs of stars have been obtained. Owing to the close proximity of the equatorial and transit instruments, we are informed that it is impossible to use them both at the same time; this should be at once remedied, for the Observatory does not seem to be supplied with many surplus instruments.

The meteorological observations have been made regularly throughout the year. We hope, now that provision has been made for supplying a rain gauge and set of thermometers for each of the coast magistracies, that the Observatory will still continue to urge the necessity of maintaining and extending the system of weather reports, in the interests of the Colony, for, as is now well known, the value of such observations is only maintained when the stations are *numerous* and well *distributed*.

GEODETIC SURVEY OF SOUTH AFRICA.—Since the issue of the last (Jan. 1891) report by H.M Astronomer, Dr. Gill, on the Geodetic Survey carried on in South Africa, the work has been progressing very successfully and swiftly, an average of five principal stations being occupied and completed every month by a single observer. On May 31, 1891, the field work as far as Modder River was completed, the site for the base line being reached the following day. Some difficulty was here encountered with regard to the selection of the position for the base, but it was eventually fixed near Kimberley, the permanent camp being fixed about eight miles from this place. The total length of the measured base was 6000 feet, and it was divided into sections of 500 feet, since this seemed "a convenient length for a forward and backward measurement in one day." The figures given in this report, although uncorrected for sea-level, &c., speak well for the accuracy of the undertaking, as will be seen from the following table. Each length of 500 feet was measured both forward and backward, and it is the differences of these measurements that are here shown:—

Section.	F − B in feet.	Section.	F − B in feet.
I.	+ 0·0025	VII.	+ 0·0014
II.	− ·0020	VIII.	+ ·0011
III.	− ·0006	IX.	+ ·0014
IV.	− ·0040	X.	+ ·0009
V.	+ ·0019	XI.	+ ·0028
VI.	− ·0019	XII.	+ ·0015

The probable error of the whole base was ± 0·028 inches. The lengths of the two sections came out as—

M_i = 2999·4445 feet
M_{ii} = 2999·7545 „

The differences between the measured and the computed lengths of Section II. through the triangulation were: by the eastern triangles $M - C_1 + 0{\cdot}0035$ feet; by the western triangles $M - C_1 - 0{\cdot}0083$ feet.

During the triangulation work several observations for latitude were made at Tafelberg, Hanover, De Put, and Kimberley Camp, the results showing, as Dr. Gill points out, "that the abnormal deviation of the plumb line found along the coast in the neighbourhood of Port Elizabeth had disappeared." The report concludes with the determinations of the observers' personal equations and two diagrams of the triangulation.

THE INTERNATIONAL CONGRESS OF EXPERIMENTAL PSYCHOLOGY.

WHEN the first Congress on this subject met in Paris in 1889 under the presidency of Prof. Ribot, and with Prof. Charles Richet for its secretary, it proved a vigorous and most successful attempt to gather together from all parts of the world the students of a difficult branch of learning in which some methods of modern physics are being used in psychology, and these methods, or at least their results, are invading the province of what our ancestors would have preferred to call metaphysics. In the opinion of many of the most thoughtful students of the subject it has been considered an important point to keep up the connection between the physiological and the psychological sides of the questions under discussion, and the present Congress under the careful and admirable presidency of Prof. Henry Sidgwick, has proved very successful on this point, and has led to much pleasant acquaintanceship between those whose general work lies in different branches of learning. At Paris the full number at the Congress was about 150, and very little notice was taken of it in England; but at this recent Congress in London there have been nearly twice as many members, and it has received 70 or 80 visitors from all parts of Europe and from the United States and Canada. The vice-presidents have been Prof. A. Bain, Prof. Baldwin, Prof. Bernheim, Prof. Ebbinghaus, Prof. Ferrier, Prof. Preyer, Prof. Delboeuf, Prof. Liégeois, Prof. Preyer, Prof. Richet, and Prof. Schäfer. Among the other well-known names of the visitors there were those of Helmholz, Binet, Ribot, Henschen (Upsala), Münsterburg (Freiburg), and among the English names Herbert Spencer, Francis Galton, Prof. Oliver Lodge, Prof. Victor Horsley, Dr. Lauder Brunton, and Dr. Hughlings Jackson. The honorary secretaries were Prof. James Sully and Mr. F. W. H. Myers. The rooms of University College were kindly lent to the Congress by Mr. Erichsen for its use during the four days of the meeting (Aug. 1-4). Prof. Sidgwick's address attracted a large audience. He expressed himself as feeling it his first duty to apologize for the choice of England as the place of meeting, inasmuch as England could not be said to be the country which had done most for experimental psychology which, in the common meaning of the terms, had been most advanced in German and French laboratories, and was making recent and rapid progress in America. However, in a slightly different sense of the word the English school of psychologists from Locke and Hume down to Bain and Herbert Spencer had been for the most part experimentalists or at least empiricists. They had before them at this Congress a very wide range of subjects, too extensive he thought on the whole to be covered by the term "Psychologie Physiologique," which had been used at Paris as the name of their first Congress, and he thought "Experimental Psychology" more appropriate. In laboratory work the leadership was taken by Germany; in hypnotism France was our master and Germany our colleague. He was glad to see some of the leaders of the Nancy School with them that day, as he thought they were taking the broader lines in the subject, and that Europe was certainly not inclined on the whole to narrow the subject. He would not attempt to discuss the larger questions at that time, but would confine himself to the harmless task of explaining the arrangements that were proposed. In the morning meetings the Congress would be divided into two sections, of which Section A would be devoted to neurology and psycho-physics, and Section B to hypnotism and cognate questions; in the afternoon there would be general meetings.

The address was very warmly received, and Prof. A. Bain, in reading the first paper took the opportunity of expressing his gratitude to Prof. Sidgwick and the secretaries for the energy they had shown in bringing together such a large group of men who were glad to make each other's acquaintance. He went on to read an interesting paper on the advantages in psychology of introspection on the one side and experiment on the other, and the ways in which one could help the other. Prof. Charles Richet went on to discuss some of the possible prospects of psychology, and to express a hope that some of the most difficult subjects, such as thought-transference and clairvoyance, might be helped by the minute study of the process of development of the human mind. Prof. Gruber (of Roumania) then gave a very vivid sketch of the remarkable association of colour with sound, which he had spent many years in observing. To a very small number among his best educated patients the sound of the vowel "e" was accompanied by a sensation of yellow colour, of "i" by blue, of "o" by black, and so on through the long list of the Roumanian vowels and diphthongs, and also to some extent with numbers. The same colour was not always induced by the same sound in different patients, but the observations had been carefully tested. Prof. Pierre Janet related in detail a long case of complete loss of memory for present events and complete incapacity for any decision (*l'aboulie*) which had been suddenly brought about by the foolish jest (on August 28, 1891) of telling her what was not true, viz. that her husband was dead. The most curious points were that the loss of memory extended backwards as far as July 14, 1891, *i.e.* of what had happened during the six weeks before the accident, though the natural memory was complete up to July 14, and the patient's sub-conscious memory of all that had happened after that could be easily demonstrated by her automatic writing and by unconscious speech in a normal or hypnotic sleep. Prof. Ebbinghaus, in criticizing the paper, remarked that the woman's state seemed best explained as a condition of such complete distraction by things without that she had no power to attend to things within. Mr. Myers cited a case described by the elder Despine in 1830, in which there was a description of double memory and double personality such that the woman in the second state could eat and drink like a drayman, but soon reverted with no memory to her first state, and asked pitifully for her usual four teaspoonfuls of arrowroot.

Next day Section A and Section B went to work separately. In Section A Prof. Henschen (Upsala) read a paper which attracted considerable attention and consisted in a very careful examination of the exact tract of the visual path in man through the brain from the eye to the visual centre in the cortex of the calcarine fissure. It was admitted that it was not in accordance with the results of physiological experiments on animals; but the arguments for its proof in man were considered quite sufficient. Prof. Horsley followed with a paper on the degree of Localization of movements and correlative sensations, which roused some discussion; and then Prof. Schäfer brought forward careful experiments to show that there was no valid reason to attribute any intellectual powers to the prefrontal lobes of the brain; and Dr. Waller ended the work of the morning by illustrating the difficulties of accurately defining the functional attributes of the cerebral cortex.

In Section B Prof. Liégeois read a paper which M. Liébeault, of Nancy, had written along with him describing a case of suicidal monomania, which they had succeeded in curing by hypnotic suggestion. The President expressed himself much interested in the paper, and regretted that they could not see Liébeault among them, for he was a man who, after twenty-five years of contempt, had succeeded in making the world realize some new methods. Dr. Frederic van Eeden (Amsterdam) read a careful report of his five years' experience of the medical cases of hypnotism along with Van Renterghem in Amsterdam. He laid stress on the care which should be taken to avoid the distrust and prejudice caused by the abnormal facts of hypnotism in public exhibitions. With the upper classes he thought hypnotism more difficult than with the lower, for they objected, rightly, to a tone of command. Psycho-therapy with them must guide and support, but not command, and that it would do so even to the extent of curing some organic disease he regarded as well proved. Virchow's cellular pathology had neglected the psychical forces of the living cell. Now that these were acknowledged some principles of the old vitalism must revive. Prof. Bernheim read another more technical paper on hysterical amaurosis, explaining it as a purely psychical state brought about by suggestion, with which Dr. Bérillon could not agree, but Prof. Bernheim replied that there was nothing abnormal in hypnotism; there was no difference between normal and hypnotic sleep, though the two states were produced by different means. Further, there was not necessarily any sleep in hypnosis. It was a pity for that reason that the word had been chosen, for hypnotism meant simply suggestibility. Prof. Delboeuf took a similar view; to hypnotize a man was only to persuade him that he could do something that he thought he could not do. Supposing the man thought he had a pain, to hypnotize him was to make him sure he had not. Dr. Bérillon preferred to define hypnotism as the psychical state in which the cerebral control had been taken away artificially, and the patient became an automaton for any use. Such automatism was not in any way necessarily injurious to the subject, and was certainly useful in some diseases.

In the general afternoon meeting there were elaborate theories of colour perception well explained to the Congress both by Prof. Ebbinghaus and by Mrs. C. L. Franklin; and Prof. Lloyd Morgan attempted the difficult task of defining the limits of animal intelligence, chiefly as shown by the dog, whom he was sorry not to be able to credit with as much power of introspection as many of his friends. After some slight discussion on this, Dr. Bramwell (of Goole) brought forward four subjects from Yorkshire, on whom he showed some of the common phenomena of hypnotism and related some of his experiences in recent medical practice, which he had been able to show to doctors in Leeds and elsewhere, *e.g.* that he had been able in a few cases to produce by hypnotism, at a time when the patient seemed fully awake and normal, a state of local anæsthesia to allow a dentist to extract seven double teeth without any pain to the patient.

On Wednesday morning, in Section A, Prof. Heynaus (of Copenhagen) read a paper on the relation of Weber's law to the phenomena of the inhibition of presentations; Dr. Mendelssohn (St. Petersburg) on the parallel law of Fechner; Dr. Verricst (Louvain) on the physiological basis of rhythmic speech; and M. Binet (Paris) on the psychology of insects, showing that in the Coleoptera the dorsal nervous centres were motor and the ventral sensory. In Section B Prof. Delboeuf pointed out the remarkable power of the somnambulist in judging of the length of passing time without any watch or instrument. He had found some simple Belgian countrywomen when hypnotized able to carry out suggestions at any time he liked to name from 300 to 3000 minutes, and he thought the subject deserved further inquiry. Prof. Hitzig (Berlin) brought forward a minute and careful physiological study of some attacks of sleep which had some resemblance to hypnotic conditions.—Mr. F. W. H. Myers showed from the reports drawn up by Mr. Kenlemans, Mrs. Verrall, and two other experimenters of some experience that in some cases, though probably only in a few, it was possible to induce hallucinations by such an experiment as crystal vision, *i.e.* the purely empirical process of looking steadily into a crystal or other clear depth or at a polished surface. These externalized images or quasi-percepts illustrated some little known points in conscious and sub-conscious memory. Prof. Pierre Janet corroborated Mr. Myers's results by some of his own, in which, for instance, dreams which had been manifest to the onlooker but unknown to the sleeper were brought within the sleeper's knowledge by gazing on a bright surface or by the essentially similar process of automatic writing. In the afternoon the President presented a very long report of careful detail of a census of hallucinations which had been agreed upon at the Congress in Paris in 1889, and which had been carried out in England by himself, in America by Professor William James, and in France by M. Marillier. The question asked in England had been, "Have you ever, while in good health, and believing yourself to be awake, seen the figure of a person or heard a voice which was not in your view referable to any external cause?" In England 17,000 answers had been obtained, and about 1 in 10 persons (taken at random) who had answered had had some such hallucination in their lives. The great majority of these hallucinations consisted of realistic appearances of living men, a small minority of dead persons, and a still smaller group of grotesque objects. A remarkable class was that of hallucinations of several persons at one time—collective hallucinations; and a still more remarkable class was of those coincidental with some distant event unknown to the percipient, such as the death of the person whose figure appeared. The President came to the conclusion that after careful allowance for all sources of error, the probability against these coincidences being chance was enormous, and if the hypothesis that they were not casual was to be accepted, the assumption of the inaccuracy of the informants and inquirers must be strained to an extreme pitch. M. Marillier explained that it had been very difficult to get any large number of answers in France because of the dislike shown by the French to answer any psychological questions about themselves.

On Thursday morning, in Section A, Dr. Donaldson gave an interesting account of the minute investigation of the brain of Laura Bridgeman, the well-known blind deaf mute, who died in 1889 in Boston. There was depression of the motor speech centre, with slender sensory nerves and somewhat thin cortex over the areas of the defective senses. In Section B Dr. Bérillon raised a lively debate by describing the good effects he had brought about by hypnotism in the education of about 250 children, who were suffering from many childish discomforts, such as night-terrors, insomnia, somnambulism, or faults, such as kleptomania, idleness, cowardice, &c. After this Mrs. H. Sidgwick gave a summary of some experiments in thought-transference she had made, with the help of Miss A. Johnson and Mr. G. A. Smith as hypnotiser. By thought-transference she meant the communication from one person whom they called the agent to another, whom they called the percipient, otherwise than through the recognized channels of sense. The successful percipients were seven in number, and had generally been hypnotised. They had succeeded in transferring numbers, mental pictures, *i.e.* mental pictures in the agent's mind, and induced hallucinations given by verbal suggestion to one hypnotic subject, and transferred by him to another. In the total number of experiments the number of failures was much larger than of successes, but as the antecedent probability could in most cases be accurately determined, the proportion of successes was amply sufficient to show that the result was not due to chance. The many precautions necessary to such experiments were described in detail. One percipient succeeded in the experiments with numbers when divided from the agent by a closed door at a distance of about 17 feet. Attention was called to the great variability of results with the same percipients and agents for which they had not been able to discover any reason. An account was added of some experiments in producing local anæsthesia under conditions apparently excluding all suggestion other than mental. The President wished to remark that he thought it important in such experiments that all the failures should be recorded as well as the successes. In the afternoon, after papers by Dr. Lightnar Witmer, Dr. Wallaschek, and Prof. von Tschisch, the President put several questions to the vote as to matters of future organization, and it was decided to hold the next international Congress in Munich in 1896, with Prof. Stumpf as President and Baron von Schrenck as secretary. A suggestion was also made that there should be an extraordinary meeting in America next year, and a small American committee was appointed to consider this. After a hearty vote of thanks to the President and Secretaries, and a brief reply, the Congress was dissolved.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, August 1.—M. de Lacaze-Duthiers in the chair.—On boron pentasulphide, by M. Moissan. If the tri-iodide of boron, instead of being treated with sulphur in the dry way at a low red heat, as in the preparation of boron trisulphide, be mixed with sulphur and dissolved in carbon bisulphide at the ordinary temperature, boron pentasulphide is obtained. It fuses at 390°, and does not pass through the pasty state. In contact with water it forms boric acid, sulphuretted hydrogen, and a precipitate of sulphur. Mercury and silver reduce it to the trisulphide, forming metallic sulphides. Heated to fusion in a vacuum it decomposes into sulphur and the trisulphide. Its density is 1·85. It is very difficult to obtain free from iodine, but in all the preparations the ratio between the boron and the sulphur has indicated the formula B_2S_5.—On the stripped plants of autumn, and their utilization as green manure, by M. P. P. Dehérain. It has been found that by planting the ground with vetch or mustard, and digging it in during the autumn, the amount of nitrogen retained in the soil was nearly doubled.—Remarks on alimentation in the Ophidia, by M. Léon Vaillant.—A report on the great anaconda of Central America kept in the reptile menagerie. Since 1885 the snake has eaten on the average five times per annum, its nourishment consisting of goats, three rabbits, and one goose. The interval between two meals was in one instance 204 days.—On symmetric tetrahedral curves, by M. Alphonse Dumoulin.—On Stokes' law, its verification, and interpretation, by M. G. Salet.—A spectrum, given by a spectroscope with quartz prisms, is received on the fluorescent substance contained in a Soret eye-piece. It is then projected transversally on to the slit of a second spectroscope. Through this the diagonal spectrum of Stokes' classical experiment is seen with perfect definition, no ray exceeding the theoretical limit. The law thus verified can also be deduced from thermodynamic considerations. According to Stokes' law, "the rays emitted by a fluorescent substance always have a smaller refrangibility than the exciting rays." If it were possible to transform yellow into violet light by fluorescence, many chemical reactions would become possible which only occur at the higher temperature at which violet appears in the spectrum. This would be equivalent to the passage of heat from a colder to a hotter body, in contradiction to the second law of thermodynamics.—Constitution of pyrogallol, by M. de Forcrand.—On Cascarine, by M. Leprince.—Physiological examination of four cyclists after a run of 397 km., by MM. Chibret et Huguet. This distance, which was covered by the youngest of the party, an Englishman of 18, in seventeen hours, was that between Paris and Clermont-Ferrand. It was found that the temperature was at the finish rather below than above the normal; that the coefficient of utilization of urinary nitrogen varied inversely as the degree of fatigue, and that therefore a decided waste of nitrogen is a concomitant of excessive fatigue. The nutriment taken during the course consisted of much alcohol, champagne, beef-tea, and Kola solution in the case of the Englishman. He and the next in speed both took Kola. The winner was extremely fatigued at the finish; the next man, a Frenchman of 28, not at all. His pulse was beating at 60, that of the former at 84. The coefficients of utilization of nitrogen were 76·32 and 58·27 per cent. respectively.—On the properties of the vapours of formol or formic aldehyde, by MM. F. Berlioz and A. A DEBATABLE LAND—PLANTS OR ANIMALS?

A Monograph of the Myxogastres. By George Massee. (London: Methuen and Co., 1892.)

THIS work is much in advance of any book in the English language treating of the perplexing group of organisms that forms its subject. The author has been in peculiarly favourable circumstances for the preparation of such a monograph, having enjoyed full access to "the splendid collection of Myxogastres in the Royal Herbarium, Kew, rich in types, and with numerous annotations by Rostafinski," as well as had "the loan or gift of valuable, and in some instances unique, specimens" from other workers in the same field in different countries. He has fully acquainted himself with the literature of the subject, and has made many personal observations on the structure, and, in some cases, on the life-history, of various types. He is thus able to bring to bear on the discussion of the problems that claim consideration a wide and varied knowledge; with the result that the book is indispensable to every student of the Myxogastres. The introductory portion will be found worth perusal by others besides specialists, as it discusses the arguments for and against the vegetable nature of the group. While accepting the view that the origin of the Myxogastres is to be found among the *Flagellatæ*, he comes to the conclusion that the sum of the characters presented by them in the reproductive phase manifests a tendency "in the direction of the vegetable kingdom, and more especially in the direction of the Fungi." But he is unable to establish strict homologies with the latter; since the Myxogastres are "a terminal group, and permit no comparisons with higher forms of the same type." In the discussion of this vexed question, Mr. Massee shows none of the virulence to which it has given rise in former times; and he endeavours to do justice in his statement to the views of De Bary, and of other supporters of the view that the organisms in question should be regarded as animals. After all, to an evolutionist at least, the distinction would appear more of verbal than of real importance.

Accepting the view that there are certain forms, of a very primitive structure, from which the animal and vegetable kingdoms have been developed in ever-increasing specialization, there is cause to expect the existence of more or less intermediate types, in which the characters at one period of their life-history are more those of animals, and at another period more plant-like. It matters little under which kingdom we agree to place them. Here, as elsewhere, Nature refuses to be bound down by rigid classification, and we must accept facts as they are, not as any *a priori* system might wish to make them. That the Myxogastres are not Fungi may be admitted; though they show a considerable similarity in various points in the course of development—a similarity clearly stated by Mr. Massee in his discussion of the whole question.

The term *Myxogastres* is employed, we infer, on the ground of priority. It possesses, however, the incidental advantage of not implying any positive view on the nature of the group, in the same way as do the terms *Myxomycetes* and *Mycetozoa*. The limits of the group are taken in this monograph in the sense employed by Rostafinski. It thus does not include the *Acrasieæ* and *Ceratium*, admitted as Mycetozoa by De Bary; nor does it make any reference to the numerous forms of the *Monadineæ*, which Zopf discusses in his "Schleimpilze" in Schenck's "Handbuch der Botanik." Thus limited, the group is more homogeneous; though the definition is, perhaps, somewhat arbitrary, and omits forms that are undoubtedly related to the more specialized types, and an English work on which would be welcome.

The author enters on somewhat slippery ground in the endeavour to explain the line of development of the Myxogastres, and also to illustrate his ideas of the relationship between the several orders. He holds that four orders can be distinguished by the presence or absence of lime in the sporangial wall, and by the presence and nature of the capillitium.

> "In each order we find the special characteristic idea evolving through a sequence of genera, the terminal one not connected with any higher order, hence the special feature terminates abruptly within the order where it originated, and it is invariably in some comparatively undifferentiated genus near the initial point of each order, that we meet with the suggestion of a new line of evolution, which, at its maximum of development, constitutes the characteristic feature of the order immediately in advance of the one from which it emanated in an incipient condition."

Turning now to the systematic portion of the work, we find that it gives abundant proofs of care and of familiarity with the several forms, based on personal examination of each. The method of description is clear, the more important characters being printed in italics. Mr. Massee recognizes fully the difficulties of determining the limits of species and of the larger groups "while the life-history of the majority of forms is still unknown," saying plainly that

> "all attempts at classification, as also the conception as to what constitutes a species, must be considered as tentative. When we are better acquainted with the main lines of development and lines of variation, also the conditions determining these variations, it is certain that the main factor in the discrimination of species will not be a one-twelfth oil-immersion objective."

Basing his acquaintance with the Myxogastres on personal examination of large numbers of examples, fresh and dried, many of the latter being authentic types, Mr. Massee does not hesitate to unite species and genera hitherto kept as distinct, but shown to be connected by fuller material. Thus several familiar names become sunk as synonyms; *e.g. Licea*, Schrad., and *Lindbladia*, Fr., are ranked under *Tubulina*, Pers. (emended). Under the generally accepted rules of nomenclature, this leads to Massee standing as the authority for many species, transferred by him, in reality, to another genus. But, besides such cases of apparent novelties, there are also a good many descriptions of *new* species in the usual sense of the term. The synonyms are carefully given under each group and species. A wise reticence has been observed in the endeavour to recognize the species meant by most of the older writers who mention the Myxogastres. The synonymy previous to Rostafinski's monograph is borrowed as a whole from that work, "without any attempt at corroboration." Mr. Massee says:—

> "I feel certain that nearly one-third of Rostafinski's work would not have been sacrificed to synonyms unless they mean something more than I have been able to discover, hence I have not felt justified in ignoring them altogether."

The geographical distribution has been worked out from the extensive collections already referred to as at the author's command.

The twelve plates, bearing 313 coloured figures by Mr. Massee himself, call for special mention as a valuable assistance to students of the Myxogastres. They deserve high praise for their accuracy and execution. The printing and get-up of the book are very satisfactory. A review would scarce be complete did it not find fault with some point or other; and we may do that part of our duty very briefly by taking exception to the rather inconvenient size (large octavo), and to the tendency in the introductory pages to let the sentences run to an inconvenient length. One, taken at random, we found to occupy twenty-five lines. There is no ground for this charge, however, as regards the descriptive portion of the monograph.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Apodidæ—a Reply.

PROF. LANKESTER'S review of my book in NATURE (p. 267) contains, as is usual with "candid opinions," a considerable number of misstatements. These compel me to ask space for a reply.

Prof. Lankester commences by stating very authoritatively that my account of the hermaphroditism of Apus is erroneous. This question, being purely a matter of evidence, can wait. My account of it in "The Apodidæ" is "meagre" because, as is clear to any one who reads the preface, I was constrained to put aside for the present all questions which did not directly bear upon the line of argument embodied in my book.

These points, however, are not serious. Let us turn, then, to the main charges which are intended to deprive my book of all claim to be a real contribution to zoological science. Prof. Lankester, after himself dethroning my title, "The Apodidæ," says that I "pose as the discoverer of a new and unsuspected agreement between the Crustacea and the Chætopoda, and that I bring forward arguments as new which have "long been effectively used" for the same purpose. It is difficult here not to accuse Prof. Lankester of deliberate misrepresentation. If he will allow me to keep my title and will read my book, he will find that I go beyond this general standpoint, and specialize the Apodidæ as the particular Phyllopods which are to be deduced from a Chætopod. Without, I believe, a single page of digression, my book discusses from beginning to end the relation of the Apodidæ to the Annelids, of the Apodidæ to Limulus, to the Trilobites, and so on. All the well-known arguments in favour of the more general proposition which deduces the Phyllopods from Annelids I have naturally adopted, adding, however, many new arguments of more or less weight in favour of my special point. Not one of these arguments does Prof. Lankester attempt to meet. The only one he refers to he wishes to claim as his own, as, indeed, he does everything else in the book "which will bear examination"! This charge of wholesale plagiarism from Prof. Lankester's articles on Apus and Limulus is the more remarkable, because my own investigations compelled me either to modify or to reject almost every position therein adopted by him. This may account for his "candid opinion," but hardly for his charge of plagiarism. The only evidence he adduces to support this charge can merely be meant to throw dust in the eyes; it is as follows:—

In describing the absence of articulations in the limbs of Apus I admitted that Prof. Lankester had noted the point (which, however, is not absolutely correct), but I added that he had failed to see its significance. Prof. Lankester resents this statement, and cites himself to show that he agreed with Claus in holding that the limbs of the Arthropoda were homologous with the parapodia of the Chætopods. This acquiescence in a general proposition does not in any way prove that he applied it to explain the special conditions of the limbs of Apus.

While I do not at all share his jealousy in matters of priority, and will gladly yield the point to him if he can base his claim on something more definite than the passage he cites, the fact that he wishes to claim this argument for his own is specially interesting. There is far more meaning in this than in his use of such expressions as "fanciful conceptions, crude speculations, and dogmatic assertions," because, if this particular argument holds—and Prof. Lankester would not claim it unless he acknowledged its validity—it goes far to show that my theory can hardly be called a "fanciful conception." The reviewer's statement that "there is no evidence" that I "made use of well-preserved material," looks as if he had not taken the trouble to read the book, and further as if he did not understand the importance of the issues at stake; the histological points, which are the only ones likely to be affected by the state of preservation of the material, are insignificant as compared with the main argument.

If, instead of indulging in such loose charges, Prof. Lankester had endeavoured to show where, in his opinion, my argument breaks down, and what are some of the more glaring misstatements in my book, which cause him to "regret" that he cannot recommend it as "a repository of fact," he would have done science (and perhaps (?) myself personally) much better service. I should also personally have been grateful to him had he himself set an example to the more "inexperienced" zoologist of "how morphological problems should be attacked." I did not, in my speculations as to the relation of Apus to the Annelids, feel inclined to follow the example set by Prof. Lankester in his own speculations as to the relations of Limulus to the Arachnids. I was especially recommended to ripen my ideas, and to publish them together in book-form. Would Prof. Lankester have advised me to publish my speculations, as he did his, in separate articles, occasionally, perhaps, advancing theories and arguments in one article which have to be withdrawn in the next? This plan may be convenient for the writer, but is most annoying to all who have to work over the same ground again.

To conclude, my book is an argument from beginning to end; the argument may be absurd, but it must be met by argument. In the meantime, until Prof. Lankester demolishes it, I have the good fortune to know that several leading zoologists, among whom Prof. Haeckel kindly permits me to mention his name, think it—well, to say the least—*not* absurd.

August 2. HENRY M. BERNARD.

Calculation of Trajectories of Elongated Projectiles.

(*Additional Note.*)

IT has been already pointed out (NATURE, March 1892, p. 474) that the range table of the 4-inch B.L. gun, selected by the authorities, afforded a more satisfactory test of the value of the coefficients of resistance than the results of the special experiments carried out with that gun in 1887. This range table was based on practice of 17/5/83, 7/3/84, and 21,23/4/84. The muzzle velocity was 1900f.s.; the weight of the shot 25lbs.; and the diameter of the shot 4in. But no information is given respecting the height of the barometer or thermometer. In this table the elevations are given at which the gun must be laid to obtain ranges of 100, 200, 300 . . . . 7600, 7700 yards, and also the time of flight for each range, expressed to the $\frac{1}{100}$th of a second for ranges below 5000 yards, and to the $\frac{1}{10}$th of a second for ranges 5000 to 7500 yards.

In calculating the ranges for elevations of 1°, 2°, 3° . . . . 20°, the temperature was supposed to be 62° F., and height of the barometer 30in., at the level of the gun. The coefficient κ was supposed to be 0·97 to adapt the tables to a head struck with a radius of two diameters.

By the use of the range table it was found what was the experimental elevation and time of flight for each of the ranges obtained by calculation.

The results of calculation and experiment are given in the following table. In column 1 the calculated ranges are specified. In columns 2 and 3 the calculated and experimental corresponding times of flight are given, and in column 4 the differences of these quantities. In columns 5 and 6 the calculated and the experimental elevations are given, and in column 7 their differences, which are due to the "jump" of the gun and to the "vertical drift" of the elongated shot. The calculated horizontal remaining velocity (column 8) is given in each case in yards per second to facilitate the expression of the small errors in time, given in column 4, in yards of range.

By the use of the general tables the time of flight over each range and the horizontal remaining velocity have been calculated (see columns 10 and 9), supposing the shot in each case to start with the horizontal muzzle velocity, and to move through air of a density corresponding to the mean height to which the shot actually rises.

6632	21·53	21·46	+0·07	16	15 0	+60	208	212	21·41
6821	22·58	22·51	+0·07	17	15 46	+74	203	207	22·34
7003	23·62	23·52	+0·10	18	16 33	+87	198	203	23·26
7221	24·75	24·71	+0·04	19	17 33	+87	192	199	24·38
7483	25·94	26·10	−0·16	20	18 47	+73	188	193	25·75

The very small differences in column 4 between the calculated and experimental times of flight for the full extent of the range table afford conclusive evidence of the accuracy of the coefficients of resistance derived from my experiments of 1867, 1868, and 1878–80.

F. BASHFORTH.

A Plea for an International Zoological Record.

BEING now for the second year one of the Recorders for our English "Zoological Record," I should like to offer a few remarks upon the disadvantages of the system of recording that prevails at present in England and abroad.

The first point to be noticed is the number of independent Records that are published. Chief among these are our *Zoological Record* and the *Zoologischer Jahresbericht*, published by the Zoological Station at Naples. Besides these there are several minor semi-private records which it does not concern us to enumerate.

The disadvantage of so many records is obvious. In the first place they are expensive, as the result of competition is to decrease the number of purchasers of each record, since comparatively few zoologists are able to purchase more than one of them. Secondly they are all in some way incomplete. Thus without going into great details it may be pointed out that the *Zoological Record* specializes upon systematic zoology, and as a result the portions devoted to animal morphology and embryology are all but useless, as a rule, to those interested in these subjects. Moreover, the systematic portion, being often undertaken by zoologists who are not professed systematists, does not appear always to give satisfaction to those it is intended to benefit. On the other hand the *Zoologischer Jahresbericht* leaves out systematic zoology entirely, which in many groups of animals cannot well be separated from other branches of study, and from the fact that it does not record palæontological papers, there are often omitted, at least in my two groups—sponges and echinoderms—many works of great morphological importance.

Some years ago a proposal was made by Dr. Dohrn and the staff of the Naples Zoological Station to unite the two records into one. The English part was to be entirely systematic, the Naples part was to be entirely morphological and physiological, and both were to be published together as parts of one record. This most excellent proposal was refused by the British zoologists, owing, apparently, to a desire to gain exclusive honour for British nationality.

I wish now to propose that this long-delayed project should be carried out, and that in future one International Zoological Record should be published. Such a record should fall into two natural parts: (1) a morphological and physiological part, and (2) a systematic part; each with its own chief editor. Seeing now that Naples is a recognized centre for zoological research, and that a modern zoologist's education is scarcely complete until he has studied there, the first part of the Record could best be done there much on the lines of the present *Jahresbericht*. On the other hand London, with the greatest systematic collection in the world and the addition of a perfect library, would naturally be the centre for the systematic part. The total result could be published in one volume, perhaps best at Leipzig, and the systematic part would be in English, while the morphological part could be in English, French, German, or whatever might be the language of the recorder, as it is now in the Naples *Jahresbericht*.

I think the advantages of such a scheme are obvious. By the combination the labour of recording would be enormously lessened, and the combined record need not be much more expensive than either one of the two now existing. At the same time authors could be encouraged to send in abstracts of their own works to one of the two editors. This would be an advantage in every way. In the first place authors would be sure of seeing a proper abstract of their papers published. I am sure it must be the experience of many who have published a memoir and afterwards read the abstract of it, that the abstract often gives a shockingly mutilated account of the results set forth in the original paper. By the omission of a qualifying phrase or sentence, an author's results are often made to appear in abstracts as absolute rubbish. I speak as one who has suffered.

On the other hand, the work of the recorder would be still further lightened by authors sending abstracts of their own works. It might be left to the editors' discretion to cut down an abstract if it was too long.

I feel confident that a scheme of combined records such as I have sketched out would cheapen the production of the Record to such an extent, that, amongst other things, it would be possible to pay a special recorder of the literature, that is to say, a person whose business it would be to go through all the periodicals and sort out the papers amongst the different recorders, as is actually done by the editor of the *Naples Jahresbericht*. In the present system of the English *Zoological Record* each recorder has to go through the whole of the periodicals, and if the group be a small one, *e.g.* sponges, the labour of searching for papers is out of proportion to the task of recording them. Moreover, it necessitates a longer or shorter residence in London near the British Museum Library, which may cost a recorder *more than he is paid* for his share of the Record. The duties of a recorder of the literature would be best undertaken by some one residing near the British Museum, as he could then get all the periodicals. During my residence in Naples last year I was unable to obtain all the periodicals in the enormous list of the *Zoological Record*, and thus I was obliged to leave out of my *Sponge and Echinoderm Record* for 1890 a great many papers which I am recording now for 1891.

A great need at the present moment is the intelligent organization of scientific research, and I venture to suggest the above scheme as an improvement upon the present organization as far as the recording of zoological literature is concerned. Perhaps in the far distant future a record of geology and botany might further be incorporated in the above scheme, to make an "International Record of the Progress of Biological Science." It is scarcely to be hoped, however, that we are within a measurable distance of such a convenience. Would it not be a reasonable thing that the Royal Society of London should initiate such a progress in the recording of scientific literature as that here advocated?

E. A. MINCHIN.

University Museum, Oxford, August 2.

Pilchards and Blue Sharks.

YOU may like to know that the pilchards in coming in on the Cornish coasts this season are followed by great quantities of blue sharks (*Squalus glaucus*) from four to nine feet in length.

Just now they are hanging about four or five miles from land, and evidently are disturbing the pilchards in their feeding very much, as they are not scattering and playing on the surface of the sea in the evening twilight as they usually do, but are keeping in closely-packed schools throughout the night; hence our fishermen are having a very uncertain time of it as the consequence, some boats having rather heavy catches, and others only a few hundred of fish. And all are complaining of the damage done to the nets by the sharp teeth of these monsters, as in attacking the pilchards in the fishermen's nets, there is no hesitancy on the part of the sharks, for the net is bitten through and carried off with the pilchards. Last Friday morning the fishing-boat *Wave* landed seven of these sharks, and the master said, had he desired it, he could have caught a dozen, or more.

MATTHIAS DUNN.

Mevagissey, Cornwall, August 16.

Aurora Borealis.

STANDING by the Hampstead Heath flagstaff last Friday evening (12th), a few minutes before ten, I witnessed a feeble but characteristic display of the Aurora Borealis. Looking to the north-west, and midway between Ursa Major and the horizon, was a speck of pale bluish-green luminousness. While wondering as to the cause, a flickering shaft of crimson-tinted light shot upward in the direction of the "Pointers." This was followed by other streamers and "glows," sometimes white, sometimes slightly coloured. Occasionally patches of hazy light would be formed, through which the stars could be seen, and once a number of horizontal bands or waves passed upward from the horizon in quick succession, travelling almost to the star G in Ursa Major before they faded away. At 10.20 p.m., when I left the spot, the streamers had apparently ceased, but the sky was still luminous. Throughout the display was very faint and the colours very weak—mere tints.

A. BUTCHER.

ON Friday evening, August 12th, between the hours of nine and ten p.m., there was visible here a magnificent display of the aurora borealis. The streamers were very bright at times, and those on each extreme were more or less reddish. I think it worth recording because of the unusual time of year for such a display. It was doubtless seen over a wide region, and the telegraph system may have had some experience of earth currents.

EDMUND MCCLURE.

Mundesley, Norfolk, August 13.

AN active aurora of great brilliancy was visible here on Friday night from nine till ten p.m. The whole realm of the sky from north-west to north-east and from horizon to zenith was filled with a vaporous and highly luminous mass with streamers and rays, the light sufficing for reading moderately large type. The streamers and rays were projected from the upper edge of an arch of dark-coloured vapours resting on the northern horizon. The sky space occupied by the points of the streamers covered the constellation Ursa Major on the west, Cassiopea on the east, and the intermediate region. Among the brilliant sheaf of white streamers an occasional dark-coloured ray shot upwards from the generating arch.

J. LLOYD BOZWARD.

Worcester, August 13.

Aurora Australis.

A FRIEND (Mr. Hamilton S. Dove) who has resided for several years in Tasmania having sent me a full account of an unusually splendid aurora recently observed by him, but which met with little notice even locally, I enclose a condensed description of it, thinking it worthy of record in your columns. In previous occurrences of Southern Aurora he had observed "only a greenish yellow light, and was very much surprised at the grand fiery-red cloud-like patches, which formed so striking a feature in this phenomenon."

WILLIAM WHITE.

The Ruskin Museum, Sheffield.

"On the night of Wednesday, May 18th, 1892, a grand display of aurora was witnessed by us in the Calder district, near the township of Wynyard, Table Cape, North-west Tasmania. The sun had set at about ten minutes to five, and the night was very clear and cold—no clouds were to be seen—with a keen frosty wind blowing from the south-west. Shortly after seven o'clock a bright light was visible above the southern horizon, somewhat similar to the light preceding sunrise. Then two broad zones of greenish light appeared, extending from the south-east to the south-west, in the form of a depressed arch, one zone being a short distance above the other, like the bands of a rainbow. At times parts of these bands faded, whilst other parts became brighter. Presently some patches of a dark-red colour, as of illuminated sunset clouds, began to appear above the zones of greenish light, spreading along, but with intervals between, the whole expanse of the zones—one specially large and deep red patch being conspicuous in the extreme south-west. These patches glowed and faded alternately in the same manner as the zones of greenish light.

"After continuing for the space of about half an hour the coloured lights gradually faded, leaving the strong whitish light which appeared at first. Towards nine o'clock, however, a further manifestation occurred, beginning with a brilliant red light in the south-east, and extending from the horizon to a considerable distance upward, resembling the glow from a huge fire. This also paled and brightened, till presently the two broad zones of greenish light again appeared, this time, however, confined chiefly to the south and south-east heavens, very little reaching south-west. After this reappearance of the zones some broad white stripes commenced to radiate from the horizon, crossing the zones more than half the way upwards to the zenith. The stripes began to appear near the red glow in the south-east, and several others occurred south-east by south, only two rather faint ones being to the west of south.

"Almost directly one of the white stripes appeared one of the red cloud-like patches came to the east of it, and gradually extended towards it, so that the sky above the zones of greenish-yellow light was eventually covered with red glowing patches and pale vertical stripes, which similarly paled and brightened.

"The later appearances, like the first, lasted for about half an hour and then disappeared, the moon rising soon afterwards.

"H. S. DOVE.
"G. W. EASTON."

Units Discussion at British Association.

REFERRING to the preliminary memorandum printed in your issue of August 4th, page 334, I wish to correct a slip in the statement about the fall between two surfaces joined by a "weber." I ought to have added, "if their area is one square centimetre." Enlargement of the area to a metre would diminish the pull to 40 tons. Also I may observe that at the meeting I did not press all the proposed resolutions, but withdrew Nos. 4, 5, 6, and 8.

OLIVER J. LODGE.

THE VARLEY TESTIMONIAL.

AN important Committee, containing among others, Lord Kelvin, Prof. Ayrton, Prof. G. Forbes, Dr. Gladstone, Prof. D. E. Hughes, Dr. J. Hopkinson, Prof. Kennedy, Prof. O. Lodge, Prof. J. Perry, Messrs. W. H. Preece, A. Siemens, A. Stroh, J. W. Swan, and Prof. S. Thompson, has been formed, to give effect to the feeling amongst some of the older members of the electrical profession that the life-long labours in electrical research of Mr. S. A. Varley should be recognised by some substantial testimonial befitting his reputation as a scientific investigator.

A brief sketch of Mr. Varley's career will serve to show what signal services he has rendered to the cause of electrical science and the honour his discoveries have conferred upon this country.

Mr. Samuel Alfred Varley was born in London in 1832, and was the third son of the late Mr. Cornelius Varley, an active man of science and an artist. In 1858, when the Atlantic cable was being constructed, he wrote a paper, read before the Institute of Civil Engineers, "On the Electrical Qualifications requisite in Long Submarine Cables," and was shortly afterwards elected an Associate Member of that Institution.

In the paper referred to above, Mr. Varley opposed the views of the electrical advisers of the company. Faraday, who had publicly supported their opinions, endorsed Mr. Varley's ideas immediately after receiving a copy of his paper. Mr. Varley followed this up by reading a second one before the Society of Arts in 1859, "On the Practical Bearing of the Theory of Electricity to Long Submarine Telegraphy." In this paper he suggested, among other things, the use of artificial lines, which have since proved of such value in connection with duplex working. In 1866 Mr. Varley discovered for himself the re-action or self-exciting principle, and at that early date constructed his first machine of the pure dynamo type, which is now in the Museum at South Kensington. His dynamo of 1866 was exhibited at the Inventions Exhibition of 1885, and for this he was awarded a gold medal.

The controversy which subsequently arose on this invention may be held to have been fitly summed up by the late Robert Sabine, C.E. (son-in-law of Sir Charles Wheatstone), in the following words :—"Professor Wheatstone says he was the first to complete and try the re-action machine. Mr. S. A. Varley was the first to put the machine officially on record in a provisional specification, dated December 24, 1866, which was, therefore, not published until July, 1867. Dr. Werner Siemens was the first to call public attention to the machine in a paper read before the Berlin Academy on the 17th January, 1867." (See *Engineering*, November, 1877.)

In 1866 he introduced needle-telegraph coils, in which soft-iron magnetically-induced needles were substituted for tempered steel needles. These induced and consequently undemagnetisable needles entirely superseded the old form introduced by Wheatstone and Cooke, and were largely adopted by the Postal Department. In the same year (1866) he designed a system of electric train inter-communication.

In the year 1875 Mr. Varley became assistant-manager of the works of the late British Telegraph Manufactory, Limited, and as the first Gramme machines constructed in England were manufactured by this firm, he had ample opportunities of studying the characteristics of both series wound machines and those having a seperate armature for excitation of the field magnets. There is scarcely a doubt that Mr. Varley's investigations at this period led to the invention of compound winding, for in 1876 he patented a series-shunt or compound-wound dynamo, and, in three legal suits, the claim that this specification first described a system of compound winding has been fully sustained. Mr. Varley has from time to time contributed papers read at the meetings of the British Association, among which may be mentioned one "On the Mode of Action of Lightning on Telegraph Circuits," wherein he described a lightning bridge designed by himself, a number of which are now doing duty, although fitted up more than twenty years ago.

But Mr. Varley's *magnum opus* is the important part which he took in the invention and perfecting of the dynamo, perhaps the most striking invention of the century, and upon this his fame as a patient, conscientious, and earnest scientific investigator of the Faraday school will permanently rest. His researches were undertaken in the true spirit of science, and no thought of self-emolument has ever caused him to deviate from the path which he has pursued throughout an eventful, although eminently simple and blameless life, a life in which self-denial and self-sacrifice have had no small share. Like many men of genius he was far ahead of the times, and has lived to see others reap the benefit of his great discoveries. His nervous and retiring disposition has for years kept him from the busy haunts of men, and to the younger generation of electricians he exists only in name, a name, however, that will live as long as the dynamo is employed in the service of man.

Subscriptions will be gladly received by the hon. treasurer, Mr. Stroh, 8 Haverstock Hill.

NOTES.

THE *Electrician* for August 5 contains an article on Lord Rayleigh, which is accompanied by a steel portrait.

AT a recent meeting of the Berlin Geographical Society, the chairman, Baron von Richthofen, announced that the society was about to publish, in commemoration of the 400th anniversary of the discovery of America, a work descriptive of the ancient manuscripts and maps in the Italian libraries relating to the history of this event. The German Emperor has promised a contribution of 15,000 marks towards the expense of the undertaking, and it is to be edited by Dr. Kretschmer. The accompanying atlas will contain thirty-five large maps, of which thirty-one are new, and will be published for the first time.

AT the lunch in the Library Hall, St. Andrews, on the 11th, to the party from the British Association, Prof. McIntosh announced that Mr. Charles Henry Gatty, of East Grinstead, had presented £1,000 for the purpose of establishing a Marine Laboratory at St. Andrews, which sum he further increased to £2,000 before the close of the day. The name of Mr. Gatty is sufficiently familiar to marine zoologists, were it only in connection with the accomplished lady (Mrs. Alfred Gatty), the favourite correspondent of Dr. George Johnston, of Berwick-on-Tweed. Mr. Gatty's munificent donation will enable St. Andrews to have a substantial and comfortable laboratory instead of the wooden building (formerly a fever hospital), which has hitherto been used for marine work since the period of the Trawling Commission under Lord Dalhousie. St. Andrews Marine Laboratory is the oldest permanent station in the country, and, as it has pre-eminent advantages in regard to varied and very rich marine fauna and flora, easy access to a fine University Library, and a University Museum—unique in certain departments, a new future is opened to it through Mr. Gatty's handsome gift. At the same meeting it was stated that the Fisheries prize of £20 given annually to the best student of Zoology (hitherto from an anonymous donor) was the gift of Mr. J. W. Woodall, of Scarborough. Both Mr. Gatty and Mr. Woodall were present.

DURING the past week the weather has been fine generally over the southern portion of the kingdom, but somewhat unsettled. The anticyclonic conditions which prevailed for a day or two in the middle of last week gave place on Friday, the 12th inst., to a south-westerly current, with showery weather, the rainfall being rather heavy in the north and west, while the low pressure over the north of Scotland caused rather strong gales and heavy seas on Saturday and Sunday. During the early part of the present week a depression advanced from the southward, occasioning unsettled weather and fog or mist in places, while exceptionally heavy rains occurred in parts of Ireland and Scotland, the amount measured at Parsonstown on Monday morning being 1·24 inches. During the week the maximum temperatures have nearly reached 80° in some parts of England and in the east of Scotland. For the week ending the 13th inst., temperature was below the mean in all districts, except the Channel Islands, where it just equalled it. The absolute minima, which were registered on the 11th, were exceedingly low for the time of year, and at many of the more inland stations frost was experienced on the grass.

THE fifth annual report of the National Association for the Promotion of Technical and Secondary Education has just been published, and satisfactory progress is shown. During the year a bi-monthly journal has been issued under the title of the *Record of Technical and Secondary Education*, in which detailed accounts of the work done by the County Councils have been given from time to time. The *Record* has to some extent relieved the pressure on the space of the report, which is shorter than its predecessors.

THE *Ceylon Observer* for July 21 has an editorial on "Marine Biological Stations," and while sympathizing with the decision of the meeting which was called together a short time ago to take steps to establish a station in the island of Jamaica, ventures the hope that Ceylon, too, may have its marine biological station, and points out how particularly well situated that island is for such an undertaking.

WE refer elsewhere to Prof. Forel's report on the present extension of the Alpine glaciers, to which, whatever the *modus operandi*, the disaster of St. Gervais was due. A letter in Tuesday's *Times* refers to Mr. Douglas Freshfield's warning that there may still be an excess of water ready to discharge itself in the neighbourhood of the Aiguille du Gouté, and states that the view has received a remarkable confirmation. While a party was breakfasting at the Pierre Pointue, which overhangs the stream that drains the eastern wing of the Glacier des Boisons, a tremendous noise suddenly brought them all—visitors and *employés* of the chalet—out upon the platform to see the violent flood of opaque brown fluid which tore down the bed of the stream which had been flowing so quietly before. No great damage seems to have been done, but certainly the occurrence will strengthen the view that careful scientific studies should be made so that complete warning may in all cases be given.

AN address on "Geological Chronology," which Prof. Young delivered to the Physical Society of Glasgow University in February last, has been published in pamphlet form by Messrs. Carter and Pratt, Glasgow.

A PRELIMINARY draft prospectus of a new physical atlas, which Messrs. J. Bartholomew and Co., Edinburgh, have in preparation, has reached us. The work will be based upon Berghaus's "Physikalischer Atlas," published by Justus Perthes, of Gotha, 1889–92, but will, we understand, be much larger and more extensive, and contain a great deal of entirely new and original matter. According to the present intentions of the compilers, the work will be issued in five separate sections as follows: (1) Geology; (2) Orography and Hydrography; (3) Meteorology and Magnetism; (4) Botany and Zoology; (5) Ethnography and Geographical Demography, and when complete may be obtained either in one complete volume, or in five smaller volumes. The joint authors will be Mr. J. G. Bartholomew and Dr. H. R. Mill, and the various sections will be revised and edited by, amongst others, Prof. Bayley Balfour, Dr. A. Buchan, Sir Archibald Geikie, Prof. James Geikie, and Dr. John Murray.

THE *Times* of Tuesday states that Lieutenant Bower has discovered in Chinese Turkestan the remains of a subterranean city, in one of the excavations near which he found a curious birch-bark manuscript, which he took with him back to India for the investigation of scholars. The manuscript is described as having been dug out of the foot of one of the curious old erections just outside a subterranean city near Kuchar. These erections are said to be about 50 feet to 60 feet high, in shape like a huge cottage loaf, built solid with sun-dried bricks, with layers of beams now crumbling away. Dr. Hoernle, who undertook the examination of the manuscript, thinks that these erections are Buddhist stupas, which often contain a chamber enclosing relics and other objects. These chambers are generally near the level of the ground, and are often excavated by persons in search of hidden treasure. There is no reason why a birch-bark manuscript, thus preserved from the chances of injury, should not last for an almost indefinite period, especially if the chamber is air-tight. Dr. Hoernle has now communicated to the Asiatic Society of Bengal the result of his examination of the manuscript. It is written in Sanscrit of a very archaic type, not in the Sarada character of Cashmere, as was at first surmised, but in the Gupta character, which is a much earlier form. Separate portions of it were written by different scribes and at different dates, and the latest portion must, he thinks, be ascribed to a period not later than the second half of the fifth century—say 475 A.D.—while the earlier portion must be referred to a date half a century earlier. The manuscript is therefore the oldest Indian manuscript, and one of the oldest manuscripts existing in the world. The manuscript consists of fifty-five leaves, all of which have now been transcribed and the greater part translated by Dr. Hoernle, and both will be published in instalments by the Asiatic Society of Bengal.

THE *Times* India correspondent gives us some important intelligence regarding Mr. Conway's exploring party in the Hindu-Kush. The party has arrived at Askoleya after making the first definitely recorded passage of the Hispar Pass—the longest glacier pass in the world. The party left Nagar on June 27, spent ten days exploring the vast system of glaciers not marked on any map which covers the north slopes of the main Hindu-Kush range in that neighbourhood. Mr. Conway ascended a difficult rock peak of 17,000 feet, and attempted the ascent of the Great Nagar Mountain, but he was driven back by a hundred yards of ice fall, that proved to be absolutely impassable. On July 11, after a day's halt at Hispar, Mr. Conway started up the great glacier and reached the foot of Nushik in three short marches. The next day being cloudy he did not go to the top of Nushik, as he had intended, but he sent a party under Mr. Rondebush to cross that pass. They took all the spare baggage and conveyed it by the Braldo Valley to Askoleya. Meanwhile Mr. Conway and Mr. M'Cormick with an Alpine guide, Zurbuggen, continued three more marches up the great Hispar glacier to the pass, which they actually crossed on July 18. The view from the pass is said to be superb, over a vast lake of snow some 300 miles in area, quite flat, surrounded by a ring of giant peaks and with a row of peaks rising like islands in the midst of it. They camped just below the pass on the east side and were overtaken by a severe snowstorm. They descended two marches down the Biafo glacier to the level of grass, whence they sent Zurbuggen to Askoleya, which he reached in one long day's march. Mr. Conway spent six days on the way, chiefly occupied in surveying, which the continued bad weather rendered difficult. The whole party re-united at Askoleya on July 26. The length of the pass from the foot of the Hispar Pass to the foot of the Biafo glacier is about ninety miles. The mercury on the pass stood at 15·85 in. No one suffered perceptibly from the rarefaction of the air.

The latest news from Etna is that Monte Gemmellaro has broken out afresh, and the great lava current that has been flowing from it has now been divided into two arms, both of which are rapidly advancing in the direction of Serra Pizzuto and Pedova, completely covering *en route* the lavas of 1886. The deluges of molten rock that have been emitted during the last month have destroyed one of the finest and most fertile districts in Sicily.

Prof. Forel has recently prepared a table (*Arch. de Sci.* July 15) showing the behaviour of the small lake at the Great St. Bernard in regard to cold since 1817. This lake is at a height of about 8000 feet, is about 24 acres in surface, and of small depth. It appears the mean duration of the frozen state is about 268 days; for nearly two-thirds of the year the lake is imprisoned "under a carapace of ice and snow." This justifies only too well the remark of the monk, "Nine months of winter and three months of bad weather." Between the earliest date of freezing (September 30) and the latest (November 6) are 36 days, the mean date being October 20. The earliest date of thawing is June 12, and the latest September 15; difference 95 days (the mean date being July 13). By grouping the dates in a series of decades (approximately) Prof. Forel finds maxima of duration of the frozen state in 1840–49 and in 1880–91, and a minimum in 1860–69. This corresponds fairly, he points out, with the phases of Brückner's cycle, according to which a maximum of cold occurred about 1850, a maximum of heat about 1860, and a maximum of cold about 1880.

By the election of the present holder—Mr. A. A. Kanthack—to the Medical Tutorship of the Liverpool University College Medical School, the John Lucas Walker Studentship in Pathology at Cambridge will shortly become vacant. The studentship is of the annual value of £250, and is tenable for three years. Candidates should send in their applications and testimonials by October 25, to Prof. Roy, F.R.S., New Museum, Cambridge.

We learn from the *British Medical Journal* that the Library of the British Medical Association has been presented with a valuable gift of a series of important works, bearing chiefly on hygiene and public medicine, from the library of the late Dr. Alfred Carpenter. The books number upwards of 250 volumes, and are the gift of Mrs. Carpenter.

An interesting account of a visit by Mr. E. Satow to the ruins of Sukkhothai and Sawankhalôk, Siam, appears in the Journal of the Society of Arts, for August 12.

A new edition—the sixth—of "The Electric Light popularly explained," by A. Bromley Holmes, has just been brought out by Messrs. Bemrose and Sons, Limited.

"Papers and Proceedings of the Royal Society of Tasmania for 1891" has just reached us, and we learn from the report that during the year six meetings were held and thirteen papers were read; the income amounted to £393, and the expenditure to £235 1*s.* 1*d.*

A Catalogue of Standard English and Foreign Books on Chemistry and the Allied Sciences has just been issued by Mr. W. F. Clay, Edinburgh.

The Annual Report of the Superintendent, Mr. J. H. Hart, on the Royal Botanic Gardens, Trinidad, for 1891, has lately been published, and much good work seems to have been accomplished during the year.

We have received from the Australian Museum, Sydney, Parts I. (Cephalopoda) and II. (Pteropoda) of the Catalogue of the Marine Shells of Australia and Tasmania, which Mr. John Brazier is compiling.

A pamphlet on "The Dairy and its Equipment, with Practical Management of Milk and Cream," which has been written by Dr. H. J. Webb (the Principal of the Aspatria Agricultural College) in conjunction with Mrs. Edward Moul, and recently issued, is full of information likely to be of use to those engaged in dairy-work.

In the *American Naturalist* for August, Dr. S. Lockwood gives a geological reason "Why the Mocking Birds Left New Jersey," and the report of Prof. Osborn's lectures on "Heredity and the Germ-Cells" is continued.

Naturae Novitates for July has reached us from the publishers, R. Friedländer & Sohn, Berlin.

Three new volumes have been added to the excellent series entitled "Encyclopédie Scientifique des Aide-Mémoire" (Gauthier-Villars)—"Notions de Chimie Agricole," by J. Schlœsing, Fils; "Les Divers Types de Moteurs à Vapeur," by E. Sauvage; "La Bière," by L. Lindet.

The additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Mr. H. D. Bowditch; a Puma (*Felis concolor*), a Tayra (*Galictis barbara*) from Brazil, presented by Mr. J. E. Wolfe; three Martineta Tinamous (*Colodromus elegans*) from Bahia Blanca, Argentina, presented by Mr. F. W. Horn; a Slender-billed Cockatoo (*Licmetis tenuirostris*) from Australia, presented by Dr. J. G. Victor Sapp; a Californian Sea Lion (*Otaria stelleri*) from the North Pacific, an Indian Chevrotain (*Tragulus meminna*, ♀) from India, deposited; an Indian Oriole (*Oriolus kundoo*), two —— Himalayan Tree Pies (*Dendrocitta himalayensis*) from India, five Black-necked Tanagers (*Euphonia nigricollis*), six Thick-billed Tanagers (*Euphonia laniirostris*), a Violet Tanager (*Euphonia violacea*), a Greenish Tanager (*Euphonia chlorotica*), a Lead-coloured Tanager (*Hypophœa chalybea*) from Brazil, purchased; a Magellanic Goose (*Bernicla magellanica*) bred in Holland, six Himalayan Tree Pies (*Dendrocitta himalayensis*) from India, received in exchange.

OUR ASTRONOMICAL COLUMN.

The Perseids.—Mr. Denning, in the August number of *The Observatory*, remarks, with reference to the radiant point of the Perseids, that "the agreement of observation and theory is not perfect, especially as regards the shower at its earlier stages and at its termination, when the displacement appears to be somewhat greater than theory requires." From observations made on August 16, 1877, the radiant he deduced was $60^\circ + 59^\circ$, the theoretical position, according to Dr. Kleiber, being $54^\circ + 59^\circ$. In 1886, on the same date, from the path of a very bright Perseid, Mr. Denning obtained a radiant point of $53^\circ + 59^\circ$, a value closely approaching the theoretical one. As Mr. Denning has reason to believe that the Perseids will continue to fall until the 22nd of this month, and as the suspected radiant for this date is about $77^\circ + 56\frac{1}{2}^\circ$, our readers will have an opportunity of either verifying this position or obtaining one more accurate.

The observations of the August meteors seem to have been sadly interfered with by the weather. So far we have received no communication respecting them.

"Himmel und Erde."—The August number of *Himmel und Erde* contains much that will be read with interest. Herr J. Plassmann contributes an article, which will be continued in the next issue, on variable and new stars, in which, after referring to the peculiar features of the late nova, he discusses the light curves of many well-known variables. A supplement to the note on the great February spot includes an illustration showing the movement in the line of sight of the F line caused by the presence of a protuberance in the region of the spot. "The Length of our Earth-days," "A Lost Comet," and "Paris Scientific Undertakings" are titles of other communications, the last of which is a brief general survey of recent additions to our knowledge about the construction and movement of the visible universe.

Astronomy at the Columbian Exposition.—Arrangements are about to be made for organizing a series of congresses or conventions to be held next year during the progress of the World's Exposition. The preliminary address of the General Committee on Mathematics and Astronomy points out that such a congress should take advantage of the presence of the leading scholars of the world for the mutual interchange of ideas by presenting and considering investigations in special lines of research.

The sections dealing with Astronomy and Astro-Physics are eight in number and are as follows:—

Astronomy.

a. History of Astronomy.
b. Astronomical Instruments.
c. Methods of Observation.
d. Physical Astronomy.
e. Observatory Buildings.

Astro-Physics.

a. Spectrum Analysis.
b. Astronomical Photography.
c. Stellar Photometry.

The address further states that advice and suggestions with regard to the general conduct of the convention are earnestly invited, while special stress is laid on the scientific questions for future discussion. The Chairmen of the Special Committees of the several subjects under the charge of the General Committee are as follows:—

Pure Mathematics.—Prof. E. H. Moore, Chicago University.
Astronomy.—Prof. G. W. Hough, Dearborn Observatory, North-western University, Evanston.
Astro-Physics.—Prof. George E. Hale, Kenwood Astro-Physical Observatory, Chicago.

Among the names in the partial lists of the Advisory Councils on these two subjects we notice those of Prof. A. Cayley and Prof. J. J. Sylvester for mathematics, and S. Copeland (Astronomer Royal for Scotland), Prof. R. S. Ball, Prof. Gill, Mr. Norman Lockyer, the Earl of Rosse, Prof. Liveing, Prof. Dewar, and Dr. Huggins.

Lunar Eclipse, May 11, 1892.—With reference to the lunar eclipse that occurred last May, *Astronomische Nachrichten* No. 3106 contains a series of accounts, which include the times of immersion and emersion of the objects on the moon's surface, gathered from the following observatories:—Bonn, Heidelberg, Breslau, Christiania, Prag, Kiel, and Kalocsa.

Numeration of Asteroids.—The *Astronomical Journal* No. 271 contains the announcement that an arrangement had been agreed upon by which the numeration of asteroids will in future be put on a sound basis. For the present Prof. Krueger will assign to these bodies the notation 1892 A, B, C...in the order in which their announcement is sent to the Telegraphische Central-Stelle, Prof. Tietzen, Director of the Rechen Institute in Berlin, in the meantime undertaking their definite numeration. This arrangement will be found to avoid all such confusion as has been experienced with regard to those asteroids about which sufficient information is not available for their orbital determinations. Although they will not now receive their numbers, they can easily be recognized by their lettering in the annual series.

THE BRITISH ASSOCIATION.

SECTION C.

Geology.

Opening Address by Prof. C. Lapworth, LL.D., F.R.S., F.G.S., President of the Section.

It has, I believe, been the rule for the man who has been honoured by election to the chair of President of the Geological Section of the British Association to address its members upon the recent advances made in that branch of geology in which he has himself been most immediately interested. It is not my intention upon the present occasion to depart from this time-honoured custom; for it has both the merit of simplicity and the advantage of utility to recommend it. In this way each branch of our science, as it becomes in turn represented, not only submits to the workers in other departments a report of its own progress, but presents by implication a broad sketch of the entire geological landscape, seen through the coloured glasses, it may be, of divisional prejudice, but at any rate instructive and corrective to the workers in other departments, as being taken from what is to them a novel and an unfamiliar point of view.

Now every tyro in geology is well aware of the fact that the very backbone of geological science is constituted by what is known as stratigraphical geology, or the study of the geological formations. These formations, stratified and unstratified, build up all that part of the visible earth-crust which is accessible to the investigator. Their outcropping edges constitute the visible exterior of our globe, the surface of which forms the physical geography of the present day, and their internal characters and inter-relationships afford us our only clues to the physical geographies of bygone ages. Within them lies enshrined all that we may ever hope to discover of the history and the development of the habitable world of the past.

These formations are to the stratigraphical geologist what species are to the biologist, or what the heavenly bodies are to the astronomer. It was the discovery of these formations which first elevated geology to the rank of a science. In the working out of their characters, their relationships, their development, and their origin, geology finds its means, its aims, and its justification. Whatever fresh material our science may yield to man's full conception of nature, organic and inorganic, must of necessity be grouped around these special and peculiar objects of its contemplation.

When the great Werner first taught that our earth-crust was made up of superimposed rock-sheets or formations arranged in determinable order, the value of his conclusions from an economic point of view soon led to their enthusiastic and careful study; and his crude theory of their successive precipitation from a universal chaotic ocean disarmed the suspicions of the many until the facts themselves had gained such a wide acceptance that denial was no longer possible. But when the greater Hutton asserted that each of these rock formations was in reality nothing more nor less than the recemented ruins of an earlier world, the prejudices of mankind at large were loosed at a single stroke. Like Galileo's assertion of the movement of the globe, this demanded such an apparently undignified and improbable mode of creation that there is no wonder that, even down to the present day, there still exist some to whom this is a hard saying, to be taken, if taken at all, in homœopathic doses and with undisguised reluctance.

Hutton, as regards his philosophy, was, as we know, far in advance of his time. With all the boldness of conviction he unflinchingly followed out these ideas to their legitimate results. He claimed that as the stratified formations were composed of similar materials—sands, clays, limestones, and muds—to those now being laid down in the seas around our present coasts, they must, like them, have been the products of ordinary natural agencies—of rain, rivers, and sea waters, internal heat and external cold—acting precisely as they act now. And further as these formations lie one below the other, in apparently endless downward succession, and all are formed more or less of these fragmentary materials, so the present order of natural phenomena must have existed for untold ages. Indeed, to the commencement of this order he frankly admits, "I see no trace of a beginning or sign of an end."

The history of the slow acceptance of Hutton's doctrines, even among geologists, is, of course, perfectly familiar to us all. William Smith reduced the disputed formations to order, and showed that not only was each composed of the ruins of a vanished land, but that each contained in its fossils the proof that it was deposited in a vanished sea inhabited by special life creation. Cuvier followed, and placed it beyond question that the fossilized relics of these departed beings were such as made it absolutely unquestionable that these creatures might well have inhabited the earth at the present day. Lyell completed the cycle by demonstrating stage by stage the efficiency of present natural agencies to do all the work required for the degradation and rebuilding of the formations. Since his day the students of stratigraphical geology have universally acknowledged that in the study of present geographical causes lies the key to the geological formations and the inorganic world of the past.

In this way the road was paved for Darwin and the doctrine of descent. The aid which had been so ungrudgingly afforded by biology to geology was repaid by one of the noblest presents ever made by one science to another. For the purposes of geology, the science of biology had practically completed a double demonstration: first, that the extinct life discernible in the geological formations was linked inseparably with the organic life of the present; and, second, that every fossil recognized by the geologist was the relic of a creature that might well have existed upon the surface of the earth at the present time. Geology repaid its obligation to biology by the still greater twofold demonstration: first, that in the economy of nature the most insignificant causes are competent to the grandest effects, if only a sufficiency of time be granted them; and, second, that in the geological formations we have the evidences of the actual existence of those mighty æons in which such work might be done.

The doctrine of organic evolution would always have remained a metaphysical dream had geology not given the time in which the evolution could be accomplished. The ability of present causes to bring about slow and cumulative changes in the species is, to all intents and purposes, a biological application of Hutton's ideas with respect to the original geological formations. Darwin was a biological evolutionist, because he was first an uniformitarian geologist. Biology is pre-eminent to-day among the natural sciences, because its younger sister, Geology, gave it the means.

But the inevitable consequence of the work of Darwin and his colleagues was that the centre of gravity, so to speak, of popular regard and public controversy was suddenly shifted from stratigraphical geology to biology. Since that day stratigraphical geology, to its great comfort and advantage, has gone quietly on its way unchallenged, and all its more recent results have, at least by the majority of the wonder-loving public, been practically ignored.

Indeed, to the outside observer it would seem as if stratigraphical geology for the last thirty years had been practically at a standstill. The startling discoveries and speculations of the brilliant stratigraphists of the end of the last century and first half of the present forced the geology of their day into the very front rank of the natural sciences, and made it perhaps the most conspicuous of them all in the eyes of the world at large. Since that time, however, their successors have been mainly occupied in completing the work of the great pioneers. The stratigraphical geologists themselves have been almost wholly occupied in laying down upon our maps the superficial outlines of the great formations, and working out their inter-relationships and subdivisions. At the present day the young stratigraphical student soon learns that all the limits of our great formations have been laid down with accuracy and clearness, and finds but little to add to the accepted nomenclature of the time.

Our palæontologists also have equally busied themselves in working out the rich store of the organic remains of the geological formations, and the youthful investigator soon discovers that almost every fossil he is able to detect in the field has already been named, figured, and described, and its place in the geological record more or less accurately fixed.

In France, in Germany, in Norway, Sweden, and elsewhere, in Canada and in the United States, work as thorough and as satisfactory has been accomplished, and the local development of the great stratified formations and their fossils laid down with detail and clearness.

Many an unfledged, but aspiring geologist, alive to these facts, and contrasting the well-mapped ground of the present time with the virgin lands of the days of the great pioneers, finds it hard to stifle a feeling of keen regret that there are nowadays no new geological worlds to conquer, no new systems to discover and name, and no strange and unexpected faunas to unearth and bring forth to the astonished light of day. The youth of stratigraphical geology, with all its wonder and freshness, seems to have departed, and all that remains is to accept, to commemorate, and to round off the glorious victories of the dead heroes of our science.

But to the patient stratigraphical veteran, who has kept his eyes open to discoveries new and old, this lull in the war of geological controversy presents itself rather as a grateful breathing time; the more grateful as he sees looming rapidly up in front the vague outlines of those oncoming problems which it will be the duty and the joy of the rising race of young geologists to grapple with and to conquer, as their fathers met and vanquished the problems of the past. He knows perfectly well that Geology is yet in her merest youth, and that to justify even her very existence there can be no rest until the whole earth-crust and all its phenomena, past, present, and to come, have been subjected to the domain of human thought and comprehension. There can be no more finality in Geology than in any other science; the discovery of to-day is merely the stepping-stone to the discovery of to-morrow; the living theory of to-morrow is nourished by the relics of its parent theory of to-day.

Now if we ask what are these formations which constitute the objects of study of the stratigraphical geologist, I am afraid that, as in the case of the species of the biologist, no two authorities would agree in framing precisely the same definition. The original use of the term *formation* was of necessity lithological, and even now the name is most naturally applied to any great sheet of rock which forms a component member of the earth-crust; whether the term be used specifically for a thin homogeneous sheet of rock like the Stonesfield slate, ranging over a few square miles; or generically, for a compound sheet of rock, like the Old Red Sandstone, many thousands of feet in thickness, but whose collective lithological characteristics give it an individuality recognizable over the breadth of an entire continent.

When Werner originally discovered that the "formations" of Saxony followed each other in a certain recognizable order, a second characteristic of a formation became superposed upon the original lithological conception—namely, that of determinate "relative position." And when William Smith proved that each of the formations of the English Midlands was distinguished by an assemblage of organic remains peculiar to itself, there became added yet a third criterion—that of the possession of "characteristic fossils."

But these later superposed conceptions of time-succession and life-type are far better expressed by dividing the geological formations into zoological *zones*, on the one hand, and grouping them together, on the other hand, into chronological *systems*. For in the experience of every geologist he finds his mind instinctively harking back to the bare lithological application of the word "formation," and I do not see that any real advantage is gained by departing from the primitive use of the term.

A *zone*, which may be regarded as the *unit* of *palæontological succession*, is marked by the presence of a special fossil, and may include one or many subordinate formations. A *system*, which is, broadly speaking, the *unit of geological succession*, includes many "zones," and often, but not always, many "formations." A *formation*, which is the *unit of geological stratigraphy*, is a rock sheet composed of many strata possessing common lithological characters. The formation may be simple, like the Chalk, or compound, like the New Red Sandstone; but, simple or compound, local or regional, it must be always recognizable, geographically and geologically, as a lithological individual.

As regards the natural grouping of these lithological individuals as such, fair progress has been made of late years, and our information is growing apace. We know that there are at any rate three main groups: 1st. The stratified formations due to the action of moving water above the earth-crust; 2nd. The igneous formations which are derived from below the earth-crust; 3rd. The metamorphic formations which have undergone change within the earth-crust itself. We know also that of these three the only group which has hitherto proved itself available for the purpose of reading the past history of the globe is that of the stratified formations.

Studying these stratified formations therefore in greater detail, we find that they fall naturally in their turn into two sets—viz., a mechanical set of pebble beds, sandstones and clays formed of rock fragments washed off the land into the waters, and an organic set of limestones, chalk, &c., formed of the shells and exuviæ of marine organisms.

But when we attempt a further division of these two sets our classification soon begins to lose its definiteness. We infer that some formations, such as the Old Red and the Triassic, were the comparatively rapid deposits of lakes and inland seas; that others, like the Coal Measures, London Clay, &c., were the less rapid deposits of lagoons, river valleys, deltas, and the like; that others, like our finely laminated shales and clays of the Silurian and Jurassic, were the slower deposits of the broader seas; and finally, that others, like our Chalk and Greensand, were possibly the extremely slow deposits of the more oceanic deeps.

Nevertheless, after looking at the formations collectively, there remains no doubt whatever in the mind of the geologist that their mechanical members are the results of the aqueous degradation of vanished lands, and that their organic members are the accumulated relics of the stony secretions of what once were living beings. Neither is there any possibility of escape from the conclusion that they have all been deposited by water in the superficial hollows of the sea-bottoms and ocean floors of the earth-crust of their time.

In the life of every individual stratified formation of the mechanical type we can always distinguish three stages: first, the stage of erosion and transportation, in which the rock fragments were worn off the rocks of the higher ground and washed down by rain and rivers to the sea; second, a stage of deposition and consolidation below the surface of the quiet waters; and third, a final stage in which the completed rock-formation was bent and upheaved, in part at least, into solid land. In the formations of the organic type three corresponding stages are equally discernible: first, the period of mineral secretion by organized beings; second, the period of deposition and consolidation; and third, the final period of local elevation in mass. But one and all, mechanical and organic alike, they bear in their composition, in their arrangement, and in their fossils, abundant and irresistible evidences that they *were* the products, and that now they *are* the memorials of the physical geography of their time.

Guided by the principles of Hutton and Lyell, geologists have worked out with great care and completeness the effects of those agencies which rule in the first of these three life-stages in the history of a mechanical formation. No present geological processes are better known to the young geologist than those of denudation, erosion, and transportation, so familiar to us in the eloquent works of our President. They form together the subject-matter of that most wonderful fascinating chapter in geology, which from its modest opening among the quiet Norfolk sandhills sweeps upwards and onwards without a break to its magnificent close on the brink of the gorge of the Colorado. But our knowledge of the detailed processes of deposition and consolidation which rule in the second stage is still exceedingly imperfect, although a flood of light has been thrown upon the subject by the brilliant results of the *Challenger* expedition. And we are compelled to admit that our knowledge of the operations of those agencies which rule in the processes of upheaval and depression is as yet almost nil; and what little we have already learnt of the effects of those agencies is the prey of hosts of conflicting theories that merely serve to annoy and bewilder the working student of the science.

But not one of the formative triad of detrition, deposition, and elevation can exist without the others. No detrition is possible without the previous upheaval of the rock-sheet, from which material can be removed; no deposition is possible without the previous depression of the rock-sheet, which forms the basin in which the fragmentary material can be laid down.

Our knowledge, therefore, of the origin and meaning of any geological formation whatever, can at most be only fragmentary until this third chapter in the life-history of the geological formation has been attacked in earnest.

Now all the rich store of knowledge that we possess respecting the first stage in the life of a geological formation has been derived from a comparison of certain phenomena which the stratigraphical geologist finds in the rock formations of the past, with correspondent phenomena which the physical geographer discovers on the surface of the earth of the present. And all that we know of the second stage again has been obtained in precisely the same way. Surely analogy and common sense both teach us that all which is likely to be of permanent value to us as regards the final stage of elevation and depression must first be sought for in the same direction.

Within the last twenty years or so many interesting and vital discoveries have been made in the stratigraphy of the rock formations, which bear largely upon this obscure chapter of elevation and depression. And I propose on this occasion that we try to summarize a few of these new facts, and then, reading them in conjunction with what we actually know of the physical geography of the present day, try to ascertain how such mutual agreement as we can discover may serve to aid the stratigraphical geologist in his interpretation of the true meaning of the geological formations themselves. We may not hope for many years to come to read the whole of this geological chapter, but we may perhaps modestly essay an interpretation of one or two of the opening paragraphs.

In the physical geography of the present day we find the exterior of our terraqueous globe divided between the two elements land and water. We know that the solid geological formations exist everywhere beneath the visible surface of the lands, but of their existence under the present ocean floor we have as yet no absolute certainty. We know both the form of the surface and the composition of the outer layers of the continental parts of the lithosphere; we only know as yet even in outline the form of the surface of its oceanic portions. The surface of each of our great continental masses of land resembles that of a long and broad arch-like form, of which we see the simplest type in the New World. The surface of the North American arch is sagged downwards in the middle into a central depression which lies between two long marginal plateaux, and these plateaux are finally crowned by the wrinkled crests which form its modern mountain systems. The surface of each of our ocean floors exactly resembles that of a continent turned upside down. Taking the Atlantic as our simplest type, we may say that the surface of an ocean basin resembles that of a mighty trough or syncline, buckled up more or less centrally into a medial ridge, which is bounded by two long and deep marginal hollows, in the cores of which still deeper grooves sink to the profoundest depths. This complementary relationship descends even to the minor features of the two. Where the great continental sag sinks below the ocean level, we have our gulfs and our Mediterraneans, seen in our type continent as the Mexican Gulf and Hudson Bay. Where the central oceanic buckle attains the water-line, we have our oceanic islands, seen in our type ocean as St. Helena and the Azores. Although these apparent crust-waves are neither equal in size nor symmetrical in form, this complementary relationship between them is always discernible. The broad Pacific depression seems to answer to the broad elevation of the Old World—the narrow trough of the Atlantic to the narrow continent of America.

Every primary wave of the earth's surface is broken up into minor waves, in each of which the ridge and its complementary trough are always recognizable. The compound ridge of the Alps answers to the compound Mediterranean trough; the continous western mountain chain of the Americas to the continuous hollow of the Eastern Pacific which bounds them; the sweep of the crest of the Himalaya to the curve of the Indo-Gangetic depression. Even where the surface waves of the lithosphere lie more or less buried beneath the waters of the ocean and the seas, the same rule always obtains. The island chains of the Antilles answer to the several Caribbean abysses, those of the Ægean Archipelago answer to the Levantine deeps.

Draw a section of the surface of the lithosphere along a great circle in any direction, the rule remains always the same: crest and trough, height and hollow, succeed each other in endless sequence, of every gradation of size, of every degree of complexity. Sometimes the ridges are continental, like those of the Americas; sometimes orographic, like those of the Himalaya; sometimes they are local, like those of the English Weald. But so long as we do not descend to minor details we find that every line drawn across the earth's surface at the present day rises and falls like the imaginary line drawn across the surface of the waves of the ocean. No rise of that line occurs without its complementary depression; the two always go together, and must of necessity be considered together. Each pair constitutes one of those *geographical units of form* of which every continuous direct line carried over the surface of the lithosphere of our globe is made up. This unit is always made up of an arch-like rise and a trough-like depression, which shade into each other along a middle line of contrary curvature. It resembles the letter S or Hogarth's line of beauty, and is clearly similar in form to the typical wave of the physicist. Here, then, we reach a very simple and natural conclusion, viz. the surface of the earth-crust of the present day resembles that of a series of crust-waves of different lengths and different amplitudes, more or less irregular and complex, it is true, but everywhere alternately rising and falling in symmetrical halves like the waves of the sea.

Now this rolling wave-like earth-surface is formed of the outcropping edges of the rock formations which are the special objects of study of the stratigraphical geologist. If, therefore, the physiognomy of the face of our globe is any real index of the character of the personality of the earth-crust beneath it, these collective geographical features should be precisely those which answer to the collective structural characters of the geological formations.

In the earlier days of geology one of the first points recognized by our stratigraphists was the fact that the formations were successive lithological sheets, whose truncated outcropping edges formed the present surface of the land, and that these sheets lay inclined at an angle one over the other, or as William Smith quaintly expressed it, like a tilted "pile of slices of bread and butter." But as discovery progressed the explanation of this arrangement soon became evident. The formations revealed themselves as a series of what had originally been deposited as horizontal sheets, lying in regular order one over the other, but which had been subsequently bent up into alternating arches and troughs (*i.e.* the anticlines and synclines of the geologist). Their visible parts, which now constitute the surface of our habitable lands, were simply those parts of the formations which are cut by the irregular plane of the present earth's surface. All those parts of the great arches and troughs formerly occurring above that plane have been removed by denudation; all those parts below that plane lie buried still, out of sight within the solid earth-crust.

Although in every geological section of sufficient extent it was seen that the anticline or arch never occurred without the syncline or trough—in other words, that there was never a rise without a corresponding fall of the stratum, yet it is only of late years that the stratigraphical geologist has come clearly to recognise the fact that the anticline and syncline must be considered together, and must be united as a single crust-wave. For the arch is never present without its complementary trough, and the two together constitute the *tectonic*, *structural*, or *orographic unit*, namely, *The Fold*, the study of which, so brilliantly inaugurated by Heim in his "Mechanismus der Gebirgsbildung," is destined, I believe, in time, to give us the clue to the laws which rule in the local elevation and depression of the earth-crust, and furnish us with the means of discovery of the occult causes which lie at the source of those superficial irregularities which give to the face of our globe its variety, its beauty, and its habitability.

We have said already that this wave or fold of the geologist resembles that of the wave of the physicist. Now we may regard such a wave as formed of two parts, the arch-like part above and the trough-like part below. The length of the wave is naturally the length of the axial line joining the outer extremities of the arch and trough, and passing through the centre, node, or point of origin of the wave itself, which bisects the line of contrary curvature. The amplitude of the wave is the height of the arch added to the depth of the trough. The arch part of such a wave, if perfectly symmetrical, may clearly be regarded as belonging either to a wave travelling to the right, in which case the complementary trough is the one in that direction, or it may be regarded as belonging to a wave travelling to the left, in which case its trough must be the one in that direction. But as in the case of the shore wave, the advancing slope of the wave is always the steeper, and the real centre of the wave must lie half-way down this steeper slope; so there is no difficulty in recognizing the centre of a geological fold and fixing the real direction of movement.

The fold of the geologist differs from the ordinary wave of the physicist, essentially in the fact that even in its most elementary conception, as that of a plate bent by a pressure applied from opposite sides, it necessarily includes the element of thickness. And this being the case, the rock sheet which is being folded and curved has different layers of its thickness affected differently. In the arch of the fold the upper layers of the rock sheet are extended, while its lower layers are compressed. On the contrary in the trough of the fold the upper layers are compressed and the lower layers are extended. But in arch and trough alike there exists a central layer, which, beyond taking up the common wave-like form, remains practically unaffected.

But the geological fold has in addition to length and thickness, the further element of breadth, and this fact greatly complicates the phenomena.

Many of the movements which take place in a rock sheet which is being folded, or in other words those produced by the bending of a compound sheet composed of many leaves, can be fairly well studied in a very simple experiment. Take an ordinary large note-book, say an inch in thickness, with flexible covers. Rule carefully a series of parallel lines across the edges of the leaves at the top of the book, about $\frac{1}{8}$ of an inch apart, and exactly at right angles to the plane of the cover. Then, holding the front edges loosely, press the book slowly from back and front into an S-like form until it can be pressed no further. As the wave grows, it will be noticed that the cross lines which have been drawn on the upper edge of the book remain fairly parallel throughout the whole of the folding process, except in the central third of the book, where they arrange themselves into a beautiful sheaf-like form, showing how much the leaves of the book have sheared or slidden over each other in this central portion. It will also be seen when the S is complete that the book has been forced into a third of its former breadth. It is clear that the wave which the book now forms must be regarded as made up of three sections: viz. a section forming the outside of the trough on the one side, and a section forming the outside of the arch on the other, and a central or common section, which may be regarded either as uniting or dividing the other two.

As this experiment gives us a fair representation of what takes place in a geological fold, we see at a glance that the geologist is forced to divide his fold into three parts—an arch limb, a trough limb, and a middle limb—which last we may call the *copula* or the *septum*, according as we regard it as connecting or dividing the other two. Our note-book experiment shows us also that in the trough limb and the arch limb the leaves or layers undergo scarcely any change of relative position beyond taking on the growing curvature of the wave. But the layers in the central part, or *septum*, undergo sliding and shearing. It will be found also, by gripping the unbound parts of the book firmly and practising the folding in different ways, that this *septum* is also a region of warping and twisting. This simple experiment should be practised again and again until all these points are apparent, and the various stages of the folding process become clear; the surface of the book being forced first into a gentle arch-like rise with a corresponding trough-like fall; then stage by stage the arch should be pushed over on to the trough until the surfaces of the two are in contact and the book can be folded no further.

In the structure of our modern mountain ranges we discover the most beautiful illustrations of the bending and folding of the rocky formations of the earth-crust. The early results of Rogers among the Alleghanies, of Lory and Favre in the Western Alps, have been greatly extended of late years by the discoveries of Heim and Baltzer in the Central Alps, of Bertrand in Provence, of Margerie in Languedoc, of Dutton and his colleagues in the western ranges of America, and of Peach and Horne and others in the older rocks of Britain. The light these researches throw upon the phenomena of mountain structure will be found admirably summarized and discussed in the works of Leconte, of Dana, of Daubrée, of Reade, of Heim, and finally in the magnificent work of Suess, the "Antlitz der Erde," of which only the first two volumes have yet appeared.

Looking first at the mountain fold in its simplest form as that of a bent rock-plate, composed of many layers which have been forced into two similar arc-like forms, the convexities of which are turned, the one upwards and the other downwards, we find in the present mountain ranges of the globe every kind represented. We commence with one in which the arch is represented merely by a gentle swell of the rock sheet, and the trough by an answering shallow depression, the two shading into each other in an area of contrary flexure. From this type we pass insensibly to others in which we see that the sides of the common limb or septum are practically perpendicular. From these we pass to folds in which the twisted common limb or septum overhangs the vertical, and so on to that final extreme, where the arch limb has been pushed completely over on to the trough limb, and all three members, as in our note-book experiment, are practically welded into one conformable solid mass.

Although the movements of these mountain folds are slow and insensible, and only effected in the course of ages, so that little or no evidence of the actual movement of any single one of them has been detected since they were first studied, yet it is perfectly plain that when we regard them collectively, we have here crust folds in every stage of their existence. Each example in itself represents some one single stage in the lifetime of a single fold. They are simply crust folds of different ages. Some are, as it were, just born; others are in their earliest youth. Some have attained their majority, some are in the prime of life, and some are in the decrepit stages of old age. Finally, those in which all three members—arch limb, trough limb, and septum—are crushed together into a conformable mass, are dead. Their life of individual movement is over. If the earth pressure increases the material which they have packed together may of course form a passive part of a later fold, but they themselves can move no more.

In many cases, due partly to the action of longitudinal pressures, the septum becomes reduced to a *plane* of contrary motion, namely—the over-fault, or thrust-plane, and the arch limb and the trough limb slide past each other as two solid masses. But here we have no longer a fold, but a fault.

We see that every mountain fold commences first as a gentle alternate elevation and depression of one or more of the component sheets of the geological formations which make up the earth-crust. This movement is due apparently to the tangential thrusts set up by the creeping together, as it were, of those neighbouring and more resistant parts of the earth-crust which lie in front of and behind the moving wave. Yielding slowly to these lateral thrusts the crest of the fold rises higher and higher, the trough sinks lower and lower, the central common limb or septum grows more and more vertical and becomes more and more strained, sheared, and twisted. As this middle limb yields, the rising arch part of the fold is forced gradually over on to the sinking trough, until at last all three members come into conformable contact and further folding as such is impossible. Movement ceases, the fold is dead.

We see also from our note-book experiment that the final result of the completion of the fold is clearly to strengthen up and consolidate that part of the crust plate to the local weakness of which it actually owed its origin and position. The fold has by its life-action theoretically trebled the thickness of that part of the earth-plate in which its dead remains now lie. If the lateral pressure goes on increasing and the layers of the earth-crust again begin to fold in the same region, the inert remains of the first fold can only move as a passive part of a newer fold: either as a part of the new arch-limb, the new trough-limb, or the new septum. As each younger and younger fold formed in this way necessarily includes a more resistant, and therefore a thicker, broader, and deeper sheet of the earth-crust, we have here the phylogenetic evolution of a whole family of crust folds, each successive member of which is of a higher grade than its immediate predecessor.

But it very rarely happens that the continuous plate in which any fold is imbedded is able to resist the crust creep until the death of the first fold. Usually, long before the first simple fold is completed, a new and a parallel one rises in front of it on the side of the trough limb, and the two grow, as it were, henceforward side by side. But the younger fold, being due to a greater pressure than the older, must of necessity be of a higher specific grade, and the two together form a generic fold in common.

Our present mountain systems are all constituted of several families of folds, all formed in this way, of different gradations of size, of different dates of origin, and of different stages of life evolution; and in each family group the members are related to each other by this natural genetic affinity.

Sometimes the new folds are formed in successive order on one side of the first fold, and then we have our unilateral (or so-called unsymmetrical) mountain groups, like those of the Jura and the Bavarian Alps. Sometimes they are formed on both sides of the original fold, and then we have our bilateral (or so-called symmetrical) ranges, like the Central Alps. In both cases the septa of the aged or dead folds are of necessary all directed inwards towards the primary fold. If, therefore, they originate only on one side of the fold, our mountain group looks unsymmetrical, with a very steep side opposed to a gently sloping side. If they grow on both sides of the original fold, we have the well-known "fan structure" of mountain ranges. In this case the whole complex range is seen at a glance to be a vast compound arch of the upper layers of the earth-crust, keyed up by the material of the dead or dying folds, which by the necessities of the case constitute mighty wedges whose apices are directed inwards towards the centre of the system. But a complete arch of this kind is in reality not a single fold, but a double one, with a septum on both sides of it; and it requires two troughs, one on each side of it, as its natural complement. The so-called unsymmetrical ranges, therefore, which are constituted merely of arch limb, trough limb, and septum, are locally the more natural and the more common.

It is clear that in the lifetime of any single fold its period of greatest energy and most rapid movement must be that of middle life. In early youth the lateral pressure is applied at a very small angle, and the tangential forces act therefore under the most disadvantageous circumstances. In the middle life of the fold the arch limb and the trough limb stand at right angles to the septum, and the work of deformation is then accomplished under the most favourable mechanical conditions and with the greatest rapidity. That is to say, the activity of the fold and the rate of movement of the septum, like the speed of the storm wind, varies directly as the gradient.

In our note-book experiment we observed that little or no change took place in the arch limb and trough limb, while the septum became remarkably sheared and twisted. The same is the case in nature, but here we have to recollect that these moving mountain folds are of enormous size, indeed actual mountains in themselves. These great arches, scores of miles in length, thousands of feet in height and thickness, must of necessity be of enormous weight, capable of crushing to powder the hardest rocks over which they move, while the thrust which drives them forward is practically irresistible. It is plain, therefore, that while the great arch limb and the trough limb of one of these mighty folds move over and under each other from opposite directions, they form together an enormous machine, composed of two mighty rollers or millstones, which mangle, roll, tear, squeeze, and twist the rocky material of the middle limb or septum, which lies jammed in between them, into a laminated mass. This deformed material, which is the characteristic product of the mountain-making forces, is, of course, made up of the stuff or the original middle limb of the fold; and whether we call it breccia, mylonite, phyllite, or schist, although it may be composed of sedimentary stuff, it is certainly no longer a *stratified* rock; and though it may have been originally purely igneous material, it is certainly no longer *volcanic*. It is now a manufactured article made in the great earth mill.

These mountain folds, however, are merely the types of folds and wrinkles of all dimensions which affect the rock formations of the earth-crust. Within the mountain chains themselves we can follow them fold within fold, first down to formations, then to strata, then to laminæ, till they disappear at last in microscopic minuteness beyond the limits of ordinary vision. Leaving these, however, for the moment, let us travel rather in the opposite direction, for these mountain folds are by no means the largest known to the stratigraphical geologist. Look at any geological section crossing the continent of North America, and it will be found that the whole of the Rocky Mountain range on its western side and the Alleghany range on the east are really two mighty compound geological anticlines, while the broad sag of the Mississippi Basin is actually a compound geological syncline made up of the whole pile of the geological formations. That is to say, the continent of North America is composed of a pair of geological folds, the two arches of which are represented by the Rockies on the one side and the Alleghanies on the other, while the intermediate Mississippi syncline is the common property of both. Here, then, we reach a much higher grade of fold than the orographic or mountain-making fold, viz. the plateau-making fold or the semi-continental fold, which, because of its enormous breadth, must include a very much thicker portion of the earth-crust than the ordinary orographic fold itself.

But which must be the real middle limbs of these two American folds, those septal areas where most work is being done and the motion is greatest?

Taught by what we have already learned of the mountain wave the answer is immediate and certain. They must be on the steeper sides of each of the two folds, namely, those which face the ocean. How perfectly this agrees with the geological facts goes without saying. It is on the steep Pacific side of the western fold that the crushing and crumpling of its rocks is the greatest. It is on the Atlantic side of the eastern fold that the contortion and the metamorphism of its rocks are at their maximum, while in the common and gently sloping trough of both folds, namely, the intermediate Mississippi Valley, the entire geological sequence remains practically unmodified throughout.

Again, which of these two American folds should be the more active at the present day? Taught by our study of the mountain wave the answer again is immediate and conclusive. It must be that fold whose septum has the steeper gradient. Geology and geography flash at once into combination. The steeper Pacific septum of the western fold from Cape Horn almost to

Alaska is ablaze with volcanoes, while the gently inclined Atlantic septum of the eastern fold from Greenland to Magellan Straits shows none, except on the outer edge of the Antilles, in the very region where the slope of the surface is the steepest. We see at a glance that the vigour of these two great continental folds, like those of our mountain waves, varies directly as the surface gradient of the septum.

But the geographical surface of North America, considered as a whole, is in reality that of a double arch, with a sag or common trough in the middle. We have seen already that this double arch must be regarded as the natural complement of the equally double Atlantic trough. Here, then, if the path of analogy we have hitherto so triumphantly followed up to this point is still to guide us, the basin of the Atlantic must be, not only in appearance, but in actuality, formed of two long minor folds of the same grade as the two that form the framework of America, but with their members arranged in reverse order. If so, their submarine septa ought also to be lines of movement and of volcanic action. And this is again the case. The volcanic islands of the Azores and St. Helena lie not exactly on the longitudinal crests of the mid-oceanic *Challenger* ridge, but upon its bounding flanks.

But we have not yet, however, finished with our simple fold. If we draw a line completely round the globe, crossing the Atlantic basin at its shallowest, between Cape Verde to Cape St. Roque, and continued in the direction of Japan, where the Pacific is at its deepest, as the trace of a great circle we find that we have before us a crust fold of the very grandest order. We have one mighty continental arch stretching from Japan to Chili, broken medially by the sag of the Atlantic trough, and this great terrestrial arch stands directly opposed to its natural complement, the great trough of the Pacific, which is bent up in the middle by the mightiest of all the submarine buckles of the earth-crust, on which stand the oceanic islands of the central Pacific.

But if this be true, then the septum of all septa on our present earth-crust must cross our grandest earth fold where the very steepest gradient occurs along this line, and it must constitute the centre-point of the moving earth fold, and of greatest present volcanic activity. And where is this most sudden of all depressions? Taught once more by our geological fold, the answer is instantaneous and incontrovertible. It is on the shores of Japan, the region of the mightiest and most active of all the living and moving volcanic localities on the face of our globe.

But the course of the line which we indicated as forming our grandest terrestrial fold returns upon itself. It is an endless fold, an endless band, the common possession of two sciences. It is geological in origin, geographical in effect. It is the *wedding-ring* of geology and geography, uniting them at once and for ever in indissoluble union.

Such an endless fold, again, must have an endless septum, which, in the nature of things, must cross it twice. Need I point out to the merest tyro in these wedded sciences that if we unite the Old and New Worlds and Australia, with their intermediate sags of the Antarctic and Indian Oceans, as one imperial earth arch, and regard the unbroken watery expanse of the Pacific as its complementary depression, then the circular coastal band of contrary surface flexure between them should constitute the moving master septum of the earth crust. This is the "Volcanic girdle of the Pacific," our "Terrestrial Ring of Fire."

Or, finally, if we rather regard the compact arch of the Old World itself as the natural complement of the broken Indo-Pacific depression, then the most active and continuous septal band of the present day should divide them. Again our law asserts itself triumphantly. It is the great volcanic and earthquake band on which are strung the Festoon Islands of Western Asia, the band of Mount St. Elias, the Aleutians, Kamtchatka, the Kuriles, the band of Fusijama, Krakatoa, and Sangir. The rate of movement of the earth's surface doubtless everywhere varies directly as the gradient.

We find, therefore, that even if we restrict our observations to the most simple and elementary conception of the rock fold as being made up of arch-limb, trough-limb, and twisting but still continuous septum, we are able to connect, in one unbroken chain, the minutest wrinkle of the finest lamina of a geological formation with the grandest geographical phenomena on the face of our globe.

We find, precisely as we anticipated, that the wave-like surface of the earth of the present day reflects in its entirety the wave-like arrangement of the geological formations below. On the land we find that the surface arches and troughs answer precisely to the grander regional anticlines and synclines of the subterranean sedimentary sequence; and it may, I believe, be regarded as certain that the submarine undulations have a similar or complementary relationship. We find in the new geology, as Hutton found in the old, that geography and geology are one. We find, as we suspected, that the physiognomy of the face of our globe is an unerring index of the solid personality beneath. It bears in its lineaments the characteristic family features and the common traits of its long line of geological ancestors.

Such, it seems to me, is an imperfect account of the introductory paragraphs of that great chapter in the New Geology now in course of interpretation by geologists of the present day; and we have translated them exactly in the old way by the aid of the only living geological language, the language of present natural phenomena, and I doubt not that sooner or later the rest of this great chapter will be read by the same simple means.

I have confined myself to-day to the discussion of the characteristics of the simple geological fold as reduced to its most elementary terms of arch, trough, and unbroken septum; for this being clearly understood, the rest naturally follows. But this twisted plate is really the key which opens the entire treasure-house of the New Geology in which lie spread around in bewildering confusion facts, problems, and conclusions enough to keep the young geologist and other scientific men busily at work for many a long year to come.

Into this treasure-house I often wander myself, in the few leisure hours that I can steal from a very busy professional life; and out of it I bring now and again heresies that sometimes amuse and sometimes horrify my geological friends. As you have so patiently listened to what I have already said, perhaps you will permit me in a few final sentences to indicate in brief some of those novelties which I see already more or less clearly, and a few of those less novel points on which it appears to me that more light is wanted. My excuse is twofold—first, to furnish material for work and controversy to the young geologists; and second, to obtain aid for myself from workers in other walks of science.

The account of the simple rock-fold I have already given you is of the most elementary kind. It presupposes merely the yielding to tangential pressure from front and back, combined with effectual resistance to sliding. But in the layers of the earth-crust there is always, in addition, a set of tangential pressures theoretically at right angles to this. The simple fold becomes a *folded fold*, and the compound septum twists not only vertically but laterally. On the surface of the globe this double set of longitudinal and transverse waves is everywhere apparent. They account for the detailed disposition of our lands and our waters, for our present coastal forms, for the direction, length, and disposition of our mountain-ranges, our seas, our plains, and lakes. The compound arch becomes a dome, its complementary trough becomes a basin. The elevations and depressions, major and minor, are usually twinned, like the twins of the mineralogist, the complementary parts being often inverted, and turned through 180° (compare Italy with the Po-Adriatic depression). Every upward swirl and eddy has its answering downward swirl. The whole surface of our globe is thus broken up into fairly continuous and paired masses, divided from each other by moving areas and lines of mountain making and crust movement, so that the surface of the earth of the present day seems to stand midway in its structure and appearance between those of the sun and the moon, its eddies wanting the mobility of those of the one and the symmetry of those of the other. In the geology of the earth-crust, also, the inter-crossing of the two sets of folds, theoretically at right angles to each other, gives rise to effects equally startling. It lies at the origin of the thrust-plane or overfault, where the septal region of contrary motion in the fold becomes reduced to, or is represented by, a *plane* of contrary motion. It allows us to connect together under one set of homologies folds and faults. The downthrow side of the fault answers to the trough, the upthrow side to the arch, of our longitudinal fold; while the fault-plane itself represents the septal area reduced to zero. The node of the fault, and the alternation and alteration of throw, are due to the effects of the transverse folding.

These transverse folds of different grades, which affect different layers of the earth-crust differentially, account also for the formation of laccolites, of granitic cores, and of petrological provinces; and they enable us also to understand many of the phenomena of metamorphism.

Of the folds of the third order I shall here say nothing; but I must frankly admit that the primal cause of all this tangential movement and folding stress is still as mysterious to me as ever. I incline to think that it is due to many causes—tidal action, sedimentation, and many others. I cannot deny, however, that it may be *mainly* the result of the contraction in diameter of our earth, due to the loss of its original heat into outer space? For everywhere we find evidences of symmetrical crushing of the earth-crust by tangential stresses. Everywhere we find proofs that different layers of that crust have been affected differentially, and the outer layers have been folded the most. We seem to be dealing not so much with a solid globe as with a globular shell composed of many layers.

Is it not just possible after all that, as others have suggested, our earth is such a hollow shell, or series of concentric shells, on the surface of which gravity is at a maximum, and in whose deepest interior it is non-existent? May this not be so also in the case of the sun, through whose spot-eddies we possibly look into a hollow interior? If so, perhaps our present nebulæ may also be hollow shells formed of meteorites; on the surfaces of these shells the fiery spirals we see would be the swirls which answer to the many twisting crustal septa of the earth. Our comets, too, in this case might be elongated ellipsoids, whose visible parts would be merely interference phenomena or sheets of differential movement.

In this case we have represented before us to-day all the past of our earth as well as its present. Uniformity and evolution are one.

Thus from the microscopic septa of the laminæ of the geological formations we pass outwards *in fact* to these moving septa of our globe, marked on land by our new mountain-chains, and on our shores by our active volcanoes. Thence we sweep, *in imagination*, to the fiery eddies of the sun, and thence to the glowing swirls of the nebulæ; and so outwards and upwards to that most glorious septum of all the visible creation, the radiant ring of the Milky Way.

Prof. George Darwin, in his address to the section of mathematical and physical science at the meeting of the British Association at Birmingham in 1886, with all the courage of genius, and the authority of one of the sons of the prophets, acknowledged that it seems as likely that "meteorology and geology will pass the word of command to cosmical physics as the converse." Behind this generous admission I shelter myself. But I feel absolutely confident that long after the physicists may have swept away these provisional astronomical suggestions as "the baseless fabric of a vision," there will still remain in the treasure-house of the geological fold a wealth of abundant material for the use of the mathematician, the physicist, the chemist, the mineralogist, and the astronomer, of the deepest interest and of the highest value.

SECTION H.

ANTHROPOLOGY.

OPENING ADDRESS BY ALEXANDER MACALISTER, M.D., F.R.S., PROFESSOR OF ANATOMY IN THE UNIVERSITY OF CAMBRIDGE, PRESIDENT OF THE SECTION.

ON an irregular and unfenced patch of waste land, situated on the outskirts of a small town in which I spent part of my boyhood, there stood a notice board bearing the inscription, "A Free Coup," which, when translated into the language of the Southron, conveyed the intimation, "Rubbish may be shot here." This place, with its ragged mounds of unconsidered trifles, the refuse of the surrounding households, was the favourite playground of the children of the neighbourhood, who found a treasury of toys in the broken tiles and oyster-shells, the crockery and cabbage-stalks, which were liberally scattered around. Many a make-believe house and road, and even village, was constructed by these mimic builders out of this varied material, which their busy little feet had trodden down until its undulated surface assumed a fairly coherent consistence.

Passing by this place ten years later I found that its aspect had changed; terraces of small houses had sprung up, mushroom-like, on the unsavoury foundation of heterogeneous refuse. Still more recently I notice that these in their turn have been swept away, and now a large factory, wherein some of the most ingenious productions of human skill are constructed, occupies the site of the original waste.

This commonplace history is, in a sense, a parable in which is set forth the past, present, and possible future of that accumulation of lore in reference to humanity to which is given the name Anthropology, and for the study of which this Section of our Association is set apart. At first nothing better than a heap of heterogeneous facts and fancies, the leavings of the historian, of the adventurer, of the missionary, it has been for long, and alas is still, the favourite playground of *dilettanti* of various degrees of seriousness. But upon this foundation there is rapidly rising a more comely superstructure, fairer to see than the original chaos, but still bearing marks of transitoriness and imperfection, and I dare hazard the prediction that this is destined in the course of time to give place to the more solid fabric of a real Science of Anthropology.

We cannot yet claim that our subject is a real science in the sense in which that name is applied to those branches of knowledge, founded upon ascertained laws, which form the subjects of most of our sister Sections; but we can justify our separate existence, in that we are honestly endeavouring to lay a definite and stable foundation, upon which in time to come a scientific Anthropology may be based.

The materials with which we have to do are fully as varied as were those in my illustration, for we as anthropologists take for our motto the sentiment of Chremes, so often quoted in this Section, *humani nihil a nobis alienum putamus*, and they are too often fully as fragmentary. The bones, weapons, and pottery which form our only sources of knowledge concerning prehistoric races of men, generally come to us as much altered from their original forms as are the rusty polyhedra which once were the receptacles for biscuits or sardines. The traditions, customs, and scraps of folk-lore which are treasures to the constructive anthropologist, are usually discovered as empty shells, in form as much altered from their original conditions as are those smooth fragments of hollow white cylinders which once held the delicate products of the factory of Keiller or Cairns.

I have said that Anthropology has not yet made good its title to be ranked as an independent science. This is indicated by the difficulty of framing a definition at the same time comprehensive and distinctive. Mr. Galton characterizes it as the study of what men are in body and mind, how they came to be what they are, and whither the race is tending; General Pitt-Rivers, as the science which ascertains the true causes for all the phenomena of human life. I shall not try to improve upon these definitions, although they both are manifestly defective. On the one side our subject is a branch of biology, but we are more than biologists compiling a monograph on the natural history of our species, as M. de Quatrefages would have it. Many of the problems with which we deal are common to us and to psychologists; others are common to us and to students of history, of sociology, of philology, and of religion; and, in addition, we have to treat of a large number of other matters æsthetic, artistic, and technical, which it is difficult to range under any subordinate category.

In view of the encyclopædic range of knowledge necessary for the equipment of an accomplished anthropologist, it is little wonder that we should be, as we indeed are, little better than smatterers. Its many-sided affinities, its want of definite limitation, and the recent date of its admission to the position of an independent branch of knowledge, have hitherto caused Anthropology to fare badly in our Universities. In this respect, however, we are improving, and now in the two great English Universities there are departments for the study of the natural history of man and of his works.

Out of the great assemblage of topics which come within our sphere, I can only select a few which seem at present to demand special consideration. The annual growth of our knowledge is chiefly in matters of detail which are dull to chronicle, and the past year has not been fertile in discoveries bearing on those great questions which are of popular interest.

On the subject of the antiquity of man there are no fresh discoveries of serious importance to record. My esteemed predecessor at the Leeds meeting two years ago, after reviewing the evidence as to the earliest traces of humanity, concluded his survey with the judgment, "On the whole, therefore, it appears to me that the present verdict as to tertiary man must be in the form of 'Not Proven.'" Subsequent research has not contributed any new facts which lead us to modify that finding. The most remarkable of the recent discoveries under this head is that of the rude implements of the Kentish chalk-plateau described by Professor Prestwich; but while these are evidently of archaic types, it must be admitted that there is even yet room for difference of opinion as to their exact geological age.

Neither has the past year's record shed new light on the darkness which enshrouds the origin of man. What the future may have in store for us in the way of discovery we cannot forecast; at present we have nothing but hypothesis, and we must still wait for further knowledge with the calmness of philosophic expectancy.

I may, however, in this connection refer to the singularly interesting observations of Dr. Louis Robinson on the prehensile power of the hands of children at birth, and to the graphic pictures with which he has illustrated his paper. Dr. Robinson has drawn, from the study of the one end of life, the same conclusion which Mr. Robert Louis Stevenson deduced from the study of his grandfather, that there still survive in the human structure and habit traces of our probably arboreal ancestry.

Turning from these unsolved riddles of the past to the survey of mankind as it appears to us in the present, we are confronted in that wide range of outlook with many problems well nigh as difficult and obscure.

Mankind, whenever and however it may have originated, appears to us at present as an assemblage of tribes, each not necessarily homogeneous, as their component elements may be derived from diverse genealogical lines of descent. It is much to be regretted that there is not in our literature a more definite nomenclature for these divisions of mankind, and that such words as *race*, *people*, *nationality*, *tribe*, and *type* are often used indiscriminately as though they were synonyms.

In the great mass of knowledge with which we deal there are several collateral series of facts, the terminologies of which should be discriminated. In the first place there are those ethnic conditions existing now, or at any other point in time, whereby the individuals of mankind are grouped into categories of different comprehension, as *clans* or families, as *tribes* or groups of allied clans, and as *nations*, the inhabitants of restricted areas under one political organization. This side of our subject constitutes Ethnology.

In the second place, the individuals of mankind may be regarded as the descendants of a limited number of original parents, and consequently each person has his place on the genealogical tree of humanity. As the successive branches became in their dispersion subjected to the influences of diverse environments, they have eventually differentiated in characteristics. To each of these subdivisions of the phylum thus differentiated the name *race* may appropriately be restricted, and the sum of the peculiarities of each race may be termed *race-characters*. This is the phylogenetic side of Anthropology, and its nomenclature should be kept clearly separate from that of the ethnological side. The great and growing literature of Anthropology consists largely of the records of attempts to discover and formulate these distinctive race-characters. *Race* and *tribe* may be terms of equal extension, but the standpoint from which these categories are viewed is essentially different in the two cases.

There is yet a third series of names in common use in Descriptive Anthropology. The languages in use among men are unfortunately numerous, and as the component individuals in each community usually speak a common language, the mistake is often made of confounding the tribal name with that of the tribal language. Sometimes these categories are co-extensive; but it is not always so, for it is a matter of history that communities have been led to adopt new languages from considerations quite independent of phylogenetic or ethnic conditions. These linguistic terms should not be confounded with the names in either of the other series, for, as my learned predecessor once said in a presidential address, it is as absurd to speak of an Aryan skull as it would be to say that a family spoke a brachycephalic language.

In the one clan there may be, by intermarriage, the representatives of different races; in the one nation there may be dissimilar tribes, each derived by composite lines of ancestry from divergent phyla, yet all speaking the same language.

We have an excellent illustration of the confusion resulting from this disregard of precision in the case of the word *Celtic*, a term which has sometimes been employed as an ethnic, sometimes as a phylogenetic, and sometimes as a linguistic species. In the last-named sense, that to which I believe the use of the name should be restricted, it is the appropriate designation of a group of cognate languages spoken by peoples whose physical characters show that they are not the descendants of one common phylum in the near past. There are fair-haired, long-headed families in Scotland and Ireland; fair, broad-headed Bretons; dark-haired, round-headed Welshmen; and dark-haired, long-headed people in the outer Hebrides, McLeans, "Sancho Panza type"—men obviously of different races, who differ not only in colour, stature, and skull-form, but whose traditions also point to a composite descent, and yet all originally speaking a Celtic tongue. The use of the word *Celtic* as if it were the name of a phylogenetic species has naturally led to hopeless confusion in the attempts to formulate race-characters for the Celtic skull—confusions of a kind which tend to bring physical anthropology into discredit. Thus Retzius characterizes the Celtic crania as being dolichocephalic, and compares them with those of the modern Scandinavians. Sir Daniel Wilson considers the true Celtic type of skull as intermediate between the dolichocephalic and the brachycephali; and Topinard figures as the typical Celtic skull that of an Auvergnat, extremely brachycephalic, with an index of 85!

Our traditional history tells that we, the Celtic-speaking races of Britain, are not of one common ancestry, but are the descendants of two distinct series of immigrants, a British and a Gaelic. Whatever may have been the origin of the former, we know that the latter are not homogeneous, but are the mixed descendants of the several Fomorian, Nemedian, Firbolg, Tuatha de Danaan, and Milesian immigrations, with which has been combined in later times a strong admixture of Scandinavian blood. It is now scarcely possible to ascertain to which of these component strains in our ancestry we owe the Celtic tongue which overmastered and supplanted the languages of the other tribes, but it is strictly in accordance with what we know of the history of mankind that this change should have taken place. We have instances in modern times of the adoption by conquered tribes of the language of a dominant invading people. For example, Mr. Hale has lately told us that the speech of the Hupas has superseded the languages of those Californian Indians whom they have subdued. In like manner, nearer home, the English language is slowly but surely supplanting the Celtic tongues themselves.

We may here parenthetically note that what has been observed in the case of language has also taken place in reference to ritual and custom. Observances which have a history and a meaning for one race have, in not a few instances, been adopted by or imposed upon other races to whom they have no such significance, and who in incorporating them give to them a new local colour. These pseudomorphs of the earlier cultures are among the most perplexing of the problems which the student of comparative religion or folk-lore has to resolve.

But we want more than a perfect nomenclature to bring Anthropology into range with the true sciences. We need a broader basis of ascertained fact for inductive reasoning in almost all parts of our subject; we want men trained in exact method who will work patiently at the accumulation, verification, and sorting of facts, and who will not prematurely rush into theory. We have had enough of the untrained writer of papers, the jerry-builder of unfounded hypotheses whose ruins cumber our field of work.

The present position of our subject is critical and peculiar; while on the one hand the facilities for anthropological research are daily growing greater, yet in some directions the material is diminishing in quantity and accessibility. We are accumulating in our museums treasures both of the structure and the works of man, classified according to his distribution in time and space; but at the same time some of the most interesting tribes have vanished, and others are rapidly disappearing or becoming fused with their neighbours. As these pass out of existence we, with them, have lost their thoughts, their tongues, and their traditions; for even when they survive, blended with other races, that which was a religion has become a fragmentary superstition, then a nursery tale or a child's game, and is destined finally to be buried in oblivion. The unifying influences of commerce, aided by steam and electricity, are effectually effacing the landmarks between people and people, so that if we are to preserve in a form fit for future use the shreds which remain of the myths, folk-lore, and linguistic usages of many of the tribes of humanity, we must be up and doing without delay. It is on this account that systematic research such as that which Mr. Risley has advocated with regard to the different races of India is of such pressing and urgent importance. It is for this reason likewise that we hail with pleasure the gathering of folk-lore while yet it survives, and welcome such societies for the purpose as the Folk-lore Congress recently inaugurated.

I have said that in the department of Physical Anthropology our facilities for research are increasing. The newly-founded anthropometric laboratories are beginning to bring forth results in the form of carefully compiled statistical tables, embodying the fruits of accurate observations, which are useful as far as they go. Were these extended in their scope the same machinery might easily gather particulars as to the physical characters of the inhabitants of different districts, which would enable the anthropologist to complete in a systematic manner the work which Dr. Beddoe had so well begun. I would commend this work to the consideration of the provincial university colleges, especially those in outlying districts.

Of all the parts of the human frame, the skull is that upon which anthropologists have in the past expended the most of their time and thought. We have now, in Great Britain alone, at least four collections of skulls, each of which includes more than a thousand specimens, and in the other great national and university museums of Europe there are large collections available for study and comparison.

Despite all the labour that has been bestowed on the subject, craniometric literature is at present as unsatisfactory as it is dull. Hitherto observations have been concentrated on cranial measurements as methods for the discrimination of the skulls of different races. Scores of lines, arcs, chords, and indexes have been devised for this purpose, and the diagnosis of skulls has been attempted by a process as mechanical as that whereby we identify certain issues of postage-stamps by counting the nicks in the margin. But there is underlying all these no unifying hypothesis, so that when we, in our sesquipedalian jargon describe an Australian skull as microcephalic, phænozygous, tapeino-dolichocephalic, prognathic, platyrhine, hypselopalatine, leptostaphyline, dolichuranic, chamæprosopic, and microseme, we are no nearer to the formulation of any philosophic concept of the general principles which have led to the assumption of these characters by the cranium in question, and we are forced to echo the apostrophe of Von Török, "Vanity, thy name is Craniology."

It was perhaps needful in the early days of the subject that it should pass through the merely descriptive stage; but the time has come when we should seek for something better, when we should regard the skull not as a whole complete in itself, nor as a crystalline geometrical solid, nor as an invariable structure, but as a marvellously plastic part of the human frame, whose form depends on the co-operation of influences, the respective shares of which in moulding the head are capable of qualitative if not of quanitative analysis. Could measurements be devised which would indicate the nature and amounts of these several influences, then, indeed, would craniometry pass from its present empirical condition, and become a genuine scientific method. We are yet far from the prospect of such an ideal system, and all practical men will realize the immense, but not insuperable, difficulties in the way of its formulation.

In illustration of the profound complexity of the problem which the craniologist has to face, I would ask your indulgence while I set out a few details to show the several factors whose influence should be numerically indicated by such a mode of measurement.

The parts composing the skull may be resolved into four sets: there is, first, the brain-case; secondly, the parts which subserve mastication and the preparation of the food for digestion; thirdly, the cavities containing the organs of the senses of hearing, sight, and smell; and fourthly, those connected with the production of articulate speech. If our measurements are to mean anything, they should give us a series of definite numbers indicating the forms, modifications, and relative size of these parts, and their settings with regard to each other and to the rest of the body.

To take the last point first, it needs but a small consideration to show that the parts of the skull are arranged above and below a certain horizontal plane, which is definite (although not easily ascertained) in every skull, human or animal. This is the plane of vision. The familiar lines of Ovid—

> Pronaque cum spectent animalia cetera terram,
> Os homini sublime dedit; cœlumque tueri
> Jussit, et erectos ad sidera tollere vultus—

are anatomically untrue, for the normal quadruped and man alike, in their most natural position, have their axis of vision directed to the horizon. Systems of measurement based upon any plane other than this are essentially artificial. There are at the outset difficulties in marking the plane accurately on the skull, and it is to be deplored that the anthropologists of different nations should have allowed themselves to be affected by extraneous influences, which have hindered their unanimous agreement upon some one definite horizontal plane in craniometry.

The Frankfort plane drawn through the upper margins of the auditory foramina and the lowest points of the orbital borders has the advantage of being easily traced and differs so little from the plane of vision that we may without substantial error adopt it.

The largest part of the skull is that which is at once the receptacle and the protector of the brain, a part which, when unmodified by external pressure, premature synostosis, or other adventitious conditions, owes its form to that of the cerebral hemispheres which it contains. Speaking in this city of George and Andrew Combe, I need not do more than indicate in this matter that observation and experiment have established on a firm basis certain fundamental points regarding the growth of the brain. The study of its development shows that the convolutioning of the cerebral hemisphere is primarily due to the connection, and different rate of growth, of the superficial layer of cells with the underlying layers of white nerve fibres; and that so far from the shape being seriously modified by the constraining influence of the surrounding embryonic skull, the form of the soft membranous brain-case is primarily moulded upon the brain within it, whose shape it may however be, to some extent, a secondary agent in modifying in later growth. We have also learned that, although in another sense from that of the crude phrenology of Aristotle, Porta, or Gall, the cerebrum is not a single organ acting as a functional unit, but consists of parts, each of which has its specific province; that the increase in the number of cells in any area is correlated with an increase in the size and complexity of pattern of the convolutions of that area; and that this in turn influences the shape of the enclosing shell of membrane and subsequently of bone.

The anatomist and the physiologist have worked hand in hand in the delimitation of these several functional areas, and pathology and surgery have confirmed what experimental physiology has taught. The topography of each part of the cerebrum, so important to the operating surgeon, should be pressed into the service of the anthropologist, whose measurements of the brain-case should have definite relation to these several areas. In the discussion which is to take place on this subject, I hope that some such relationships will be taken account of. This is not the place to work out in detail how this may be done; I only desire to emphasize the fundamental principle of the method.

The second factor which determines the shape of the individual skull is the size of the teeth. That these differ among different races is a matter of common observation; thus the average area of the crowns of the upper-jaw teeth in the male Australian is 1,536 sq. mm., while in the average Englishman it is only 1,286 sq. mm., less than 84 per cent. of that size.[1]

It is easy to understand how natural selection will tend to increase the size of the teeth among those races whose modes of feeding are not aided by the cook or the cutler; and how, on the other hand, the progress of civilised habits, assisted by the craft of the dentist, interferes with the action of selection in this matter among the more cultured races.

For larger teeth a more extensive alveolar arch of implantation is necessary; and as the two jaws are commensurately developed, the lower jaw of the macrodontal races exceeds that of the meso- or microdontal races in weight. Thus that of a male Australian exceeds that of the average Englishman in the proportion of 100 : 91.

To work this heavier jaw more powerful muscles are needed.

---

[1] These and the succeeding averages are from my own measurements, taken from never less than ten individual cases.

In the average well-developed Englishman with perfect teeth the weight of the fleshy portion of the great jaw-muscles, masseters and temporals, is 60 grammes, while the weight of those as ascertained in two Australians was 74 grammes.

Correlated with this greater musculature a sharper definition of the areas for the attachments of the jaw-muscles is required. The muscular fascicles are approximately of uniform size in both microdonts and macrodonts, as the range of motion of the jaw differs little in different races; but when the skull is smaller on account of the smaller size of the brain which it contains, the temporal crest ascends higher on the side-wall. In the average Englishman the temporal crests at their points of greatest approximation anteriorly across the brows are 112 mm. apart, but in the Australian they are only separated by 103 mm.: the interstephanic distances in these two are respectively 132 and 114 mm.

The more powerful stroke of the mandibular teeth upon the anvil of the upper-jaw teeth in macrodonts renders necessarily a proportionally stronger construction of the bases of support for the upper alveolar arch. In any skull this arch requires to be solidly connected to the wall of the brain-case to which the shock of the impact is ultimately transmitted, and in order to protect from pressure the delicate intervening organs of sight and smell, the connection is accomplished by the reversed arches of the infraorbital margins with their piers, malar and maxillary, founded on the frontal angular processes. These foundations are tied together by the strong supraorbital ridge, so that the whole orbital edge is a ring, made up of the hardest and toughest bone in the skeleton.

A twofold modification of this arrangement is required in the macrodont skull. The bony circum-orbital ring becomes stronger, especially along its lateral piers; and also as the alveolar arch is longer, and consequently projects farther forward, its basis of support must be extended to meet and bear the malar and maxillary piers. But macrodonts are often microcephalic, and therefore the frontal region of the skull must be adjusted to form a foundation for this arch. In the average English male skull, held with its visual axes horizontal, a perpendicular dropped from the anterior-surface of the fronto-nasal suture will cut the plane of the alveolar arch between the premolar teeth or through the first premolar. In an Australian skull the perpendicular cuts the horizontal plane at the anterior border of the first molar teeth.

It is obvious, therefore, that to ensure firmness, the piers of the arches must be obliquely set; hence the jaw is prognathous, but it is also needful that the supra-orbital arcade should be advanced to meet and bear these piers, as the mandibular stroke is always vertical.

But the inner layer of the skull is moulded on the small frontal lobes of the brain, so this forward extension must affect only the much thicker and tougher outer table of the skull, which, at the period of the second dentition, here separates from the inner table, the interval becoming lined by an extension of the mucosa of the anterior ethmoidal cell. In this way an air space, the frontal sinus, is formed, whose development is thus directly correlated to the two factors of brain development and size of the teeth. If the frontal lobes are narrow in a macrodont skull, then the foundations of the outer or malar piers of the orbital arch must be extended outwards as well as forwards, the external angular process becoming a prominent abutment at the end of a strong low-browed supraorbital arch, whose overhanging edge gives to the orbital aperture a diminished vertical height.

The crania of the two most macrodont races of mankind, Australian and African, differ in the relation of the jaw to the frontal bone. In the microcephalic Australian, the maxillæ are founded upon the under side of the shelf-like projection of the outer table of the frontal, which juts out as a buttress to bear it. On the other hand the nasal processes of the mesocephalic negro ascend with greater obliquity to abut on the frontal, and have, by their convergence, crushed the nasal bones together, and caused their coalescence and diminution.

The crania of the two most microcephalic races present distinctive features of contrast along the same lines. The Bushman's skull is usually orthognathous, with a straight forehead and a shallow frontonasal recess, while the Australian skull is prognathous with heavy overhanging brows. These conditions are correlated to the mesodontism of the Bushman and the macrodontism of the Australian respectively.

In the course of the examination of the relations of brain development to skull growth, some interesting collateral points are elicited. The frontal bone grows from lateral symmetrical centres, which medially coalesce, union taking place usually between the second and sixth years of age. It has been noticed by anthropologists that metopism, as the anomalous non-union of the halves of this bone has been termed, is rare among microcephalic races, occurring only in about 1 per cent. among Australian skulls. Increased growth of the frontal lobes as the physical accompaniment of increased intellectual activity interposes an obstacle to the easy closure of this median suture, and so in such races as the ancient Egyptian, with a broader forehead, metopism becomes commoner, rising to 7 per cent. In modern civilised races the percentage ranges from 5 to 10. In following out the details of this enumeration, I have spoken as if the microdontal condition had been the primary one, whereas all the available evidence leads to show that the contrary was the case. The characters of all the early crania, Neanderthal Engis, and Cromagnon, are those of macrodonts. The progress has been from the macrodont to the microdont, as it probably was from the microcephalic to the macrocephalic.

The effects of the variations in size of the teeth are numerous and far-reaching. The fluctuation in the weight of the jaw depending on these variations has an important influence on the centre of gravity of the head, and affects the set of the skull on the vertebral column. This leads to a consequent change in the axes of the occipital condyles, and it is one of the factors which determines the size of the neck-muscles, and therefore the degree of prominence of the nuchal crests and mastoid process.

As the teeth and alveolar arches constitute a part of the apparatus for articulate speech, so these varieties in dental development are not without considerable influence on the nature of the sound produced. The necessarily larger alveolar arch of the macrodont is hypseloid or elliptical, more especially when it has to be supported on a narrow frontal region, and this is associated with a more extensive and flatter palatine surface. This, in turn, alters the shape of the mouth cavity, and is associated with a wide flat tongue, whose shape participates in the change of form of the cavity of which it is the floor. The musculature of the tongue varies with its shape and its motions, upon which articular speech depends, become correspondingly modified. For example, the production of the sharp sibilant S requires the approximation of the raised flexible edge of the tongue to the inner margins of the teeth behind the canines, and to the palatine margin close behind the roots of the canine and lateral incisor teeth. This closes the vocal tube laterally, and leaves a small lacuna about 5 mm. wide anterially, through which the vibrating current of air is forced. A narrow strip of the palate behind the medial halves of the median incisors bounds this lacuna above, and the slightly concave raised tongue-tip limits it below.

With the macrodont alveolar arch, and the correspondingly modified tongue, sibilation is a difficult feat to accomplish, and hence the sibilant sounds are practically unknown in all the Australian dialects.

It is worthy of note that the five sets of muscular fibres, whose function it is to close laterally the flask-like air-space between the tongue and the palate, are much less distinct and smaller in the tongues of the Australians which I have examined than in the tongues of ordinary Europeans.

There is a wide field open to the anatomical anthropologist in this investigation of the physical basis of dialect. It is one which requires minute and careful work, but it will repay any student who can obtain the material, and who takes time and opportunity to follow it out. The anatomical side of phonology is yet an imperfectly known subject, if one may judge by the crudeness of the descriptions of the mechanism of the several sounds to be found even in the most recent text-books. As a preliminary step in this direction we are in urgent need of an appropriate nomenclature and an accurate description of the muscular fibres of the tongue. The importance of such a work can be estimated when we remember that there is not one of the 260 possible consonantal sounds known to the phonologist which is not capable of expression in terms of lingual, labial, and palatine musculature.

The acquisition of articulate speech became possible to man only when his alveolar arch and palatine area became shortened and widened, and when his tongue, by its accommodation to the modified mouth, became shorter and more horizontally flattened, and the higher refinements of pronunciation depend for their production upon more extensive modifications in the same directions.

I can only allude now very briefly to the effects of the third set of factors, the sizes of the sense organs, on the conformation of the skull. We have already noted that the shape and the size of the orbital opening depend on the jaw as much as on the eye. A careful set of measurements has convinced me that the relative or absolute capacity of the orbital cavity is of very little significance as a characteristic of race. The microseme Australian orbit and the megaseme Kanaka are practically of the same capacity, and the eyeballs of the two Australians that I have had the opportunity of examining are a little larger than those of the average of mesoseme Englishmen.

The nasal fossæ are more variable in size than the orbits, but the superficial area of their lining and their capacity are harder to measure, and bear no constant proportion to the size of their apertures, because it is impossible without destroying the skull to shut off the large air sinuses from the nasal fossæ proper for purposes of measurement. Thus the most leptorhine of races, the Esquimaux, with an average nasal index of 437 has a nasal capacity of 55 c.c.m., equal to that of the platyrhine Australian, whose average is 54·5, and both exceed the capacity of the leptorhine English, which average about 50 c.c.m. There is an intimate and easily proved connection between dental size and the extent of the nasal floor and of the pyriform aperture.

These are but a few of the points which a scientific craniometry should take into consideration. There are many others to which I cannot now refer, but which will naturally occur to the thoughtful anatomist.

In this rapid review of the physical side of our subject the study of these race-characters naturally suggests the vexed question as to the hereditary transmission of acquired peculiarities. This is too large a controversy for us now to engage in, but in the special instances before us there are grounds for the presmption that these characters of microdontism and megacephaly have been acquired at some stage in the ancestral history of humanity, and that they are respectively correlated, with diminution of use in the one case, and increase of activity in the other. It is a matter of observation that these qualities have become hereditary, and the point at issue is not the fact, but the mechanism, of the transmission. We know that use or disuse affects the development of structure in the individual, and it is hard to believe that the persistent disuse of a part through successive generations does not exercise a cumulative influence on its ultimate condition.

There is a statement in reference to one of these characters which has gained an entrance into the text-books, to the effect that the human alveolar arch is shortening, and that the last molar tooth is being crowded out of existence. I have examined 400 crania of men of the long, and round-barrow races, Romano-British and early Saxon, and have not found among all these a single instance of absence of the third molar or of overcrowded teeth. On the other hand, out of 200 ancient Egyptian skulls, 9 per cent. showed displacement or disease, and 1½ per cent. show the want of one molar tooth. Out of 200 modern English skulls there was no third molar tooth in 1 per cent. So far this seems to confirm the current opinion.

Yet the whole history of the organism bears testimony to the marvellous persistence of parts in spite of contumely and disuse. Take, for example, the present position of the little toe in man. We know not the condition of this digit in prehistoric man, and have but little information as to its state among savage tribes at the present day, but we do know that in civilised peoples, whose feet are from infancy subjected to conditions of restraint, it is an imperfect organ—

> Of every function shorn
> Except to act as basis for a corn.

In 1 per cent. of adults the second and third joints have ankylosed, in 3 per cent. the joint between them is rudimentary, with scarcely a trace of a cavity, in 20 per cent. of feet the organ has lost one or more of its normal complement of muscles. But though shorn of some of its elements, and with others as mere shreds, the toe persists, and he would be a bold prophet who would venture to forecast how many generations of booted ancestry would suffice to eliminate it from the organization of the normal man.

Nevertheless, although it is difficult to demonstrate, in the present imperfect state of knowledge, the method whereby race-characters have originated, I think that the most of our anthropologists at least covertly adopt the philosophy of the ancient proverb, "The fathers have eaten sour grapes and the children's teeth are set on edge."

But there are other branches of anthropology of far greater interest than these simple problems upon which we have tarried so long. The study of man's intellectual nature is equally a part of our subject, and the outcomes of that nature are to be traced in the tripartite record of human progress which we call the history of culture. It is ours to trace the progress of man's inventions, and their fruits in language and the arts, the direct products of the human mind. It is also ours to follow the history of man's discovery of those secrets of nature to the unfolding of which we give the name of science. The task is also ours to inquire into that largest and most important of all sections of the history of culture which deals with the relation of human life to the unseen world, and to disentangle out of the complex network of religion, mythology, and ritual those elements which are real truths, either discovered by the exercise of man's reason, or learned by him in ways whereof science takes no account, from those adventitious and invented products of human fear and fancy which obscure the view of the central realities. In this country it matters less that our time forbids us to wander in these fascinating fields wherein the anthropologist loves to linger, as the munificent benefaction of Lord Gifford has ensured that there shall he an annual fourfold presentation of the subject before the students of our Scottish universities. There is no fear that interest in these questions will flag for want of diversity in the method of treatment or of varieties in the standpoints of the successive Gifford lecturers.

From the ground of our present knowledge we can but faintly forecast the future of Anthropology, when its range is extended by further research, and when it is purged of fancies, false analogies, and imperfect observations. It may be that there is in store for us a clearer view of the past history of man, of the place and time of his first appearance, of his primitive character, and of his progress. But has this knowledge, interesting as it may be for its own sake, any bearing on the future of mankind? Hitherto growth in knowledge has not been accompanied with a commensurate increase in the sum of human happiness, but this is probably due to the imperfection which characterises even our most advanced attainments. For example, while the medical and sanitary sciences, by their progress, are diminishing the dangers which beset humanity, they have also been the means of preserving and permitting the perpetuation of the weaklings of the race, which, had natural selection exercised its unhindered sway, would have been crushed out of existence in the struggle for life.

It is, however, of the essence of true scientific knowledge, when perfected, that it enables us to predict, and if we ever rise to the possession of a true appreciation of the influences which have affected mankind in the past, we should endeavour to learn how to direct these influences in the future that they shall work for the progress of the race. With such a knowledge we shall be able to advance in that practical branch of Anthropology, the science of education; and so to guide and foster the physical, intellectual, and moral growth of the individual that he will be enabled to exercise all his powers in the best possible directions. And lastly, we shall make progress in that kindred department, Sociology, the study of which does for the community what the science of education does for the individual. Is it a dream that the future has in store for us such an Anthropological Utopia?

PHYSICS AT THE BRITISH ASSOCIATION.

THE mathematicians and physicists of the British Association could not have had better accommodation than that which was placed at their disposal in Edinburgh. The physics lecture-room of a University, with its appropriate fittings and appliances, is their ideal environment. Almost all the leading British physicists were present, the chief absentee of note being Lord Rayleigh, and foreign men of science were well represented by such men as Profs. von Helmholz, Wiedemann, Ostwald, and Du Bois, from Germany; M. Guillaume, from France; Schoute, from Holland; and Michelson, from America.

The *Discussion on a National Physical Laboratory* was one of the most important.

The speakers were Oliver Lodge, Glazebrook, von Helmholz, Lord Kelvin, Rücker, Dr. John Ince, Fitzgerald, Stokes, Carey Foster, Ayrton, and the President.

Prof. Lodge opened the discussion by giving an outline of the work which might be done in such a laboratory. The work should include the accurate determination of physical constants, the maintenance of standards, and the issue or verification of certified copies, the continuous recording of certain special phenomena, the conduction of certain special experimental inquiries, more particularly such as might have to be carried on years or even centuries; the taking up and completing of lines of research already developed by amateurs (or even in well-equipped laboratories) to that point at which it was impossible for them, unaided, to proceed farther.

Mr. Glazebrook described the work done at the Cavendish Laboratory. A part of this work consists in the testing of units of electrical resistance and electromotive force. In many cases it is quite impossible (in view of the more proper work of the laboratory) to give the necessary time for the proper carrying out of this work—which should be undertaken by a National Laboratory.

Prof. von Helmholz stated that one of the chief causes for the setting up of the National Physical Laboratory at Berlin was the desire of the Government that mechanicians should be assisted in their work by means of properly conducted scientific research and superintendence. It was necessary also that proper headquarters should exist for the construction and control of standards. The directors are entirely free from any duties of teaching, no systematic instruction being given in the laboratory. A large part of the work done consists in standardizing of thermometers. In the first year of the institution 90,000 were tested. Electrical apparatus, steam engine indicators, and standard lights for gas and electric companies, are also tested; and a considerable amount of thermodynamical work is undertaken with a view to practical improvements. £2500 are spent annually upon apparatus and work alone, exclusive of salaries.

Lord Kelvin said that it was a matter of great importance to the nation that its artizans should have as good scientific direction for their work as the artizans of Germany have for theirs.

Prof. Rücker said that it was by no means gratifying that it was necessary to send thermometers to Paris in order that they should be compared with the air thermometer. It would be of great advantage to have a national institution worked largely in connection with the Royal Society.

Prof. Fitzgerald, among other things, said that he doubted if the House of Commons was sufficiently educated to understand that the advance of scientific work was of national value.

The Discussion on Nomenclature of Units was opened by Prof. Oliver Lodge on lines recently indicated in NATURE.

Dr. Hopkinson and Dr. Preece criticized the proposed changes, maintaining that the time had not yet arrived when they could be advantageously introduced, even if they were satisfactory, which was very questionable except in one or two cases.

Dr. du Bois also spoke in opposition to the proposed changes, remarking that, even if accepted in Britain, they certainly would not be favoured in Germany. The discussion then dropped.

The Report on Underground Temperature dealt with observations made in a boring at Wheeling, West Virginia. The well had been sunk by a company to a depth of 4500 feet. The company decided to abandon it at this stage; but on request the boring was continued to a much greater depth for the purpose of the scientific observations. During last summer observations of temperature were made at successive depths of 125 feet down to the bottom. The surface temperature being 51°, at a little more than 1000 feet below the surface, 68°·75 were registered. At 3000 feet and 4000 feet respectively, 87° and 102° were observed; and at the bottom of the well the temperature was 110°·15. The rate of increase grows with the depth. Between 1590 feet and 1835 feet, the average rate was 1° per 92 feet; between 1835 feet and 2486 feet it was 1° per 84·5 feet. This increased until at the foot the rate was 1° per 58 feet. The average rate was 1° per 72 feet.

Report on the Discharge of Electricity from Points.—As the result of the experiments made it was found that disturbing influences, which had little or no effect at the cathode, had a powerful effect when applied to the anode, so as even to prevent the passage of sparks. Experiments were also made with the view of determining the quantity of gas concerned in the passage of a given quantity of electricity.

Report on Electrical Standards.—The committee which submitted this report had a meeting at Edinburgh, which was attended by a number of foreigners. As a result of this meeting they agreed to the following resolutions:—(1) That the resistance of a specified column of mercury be adopted as the practical unit of resistance; (2) That 14·4521 grammes of mercury in the form of a column of uniform cross-section, 106·3 cm. in height, at 0° C., be the specified column; (3) That standards in mercury, or solid metal having the same resistance as this column, be made and deposited as standards of resistance for industrial purposes; (4) That such standards be periodically compared with each other, and also that their values be redetermined at intervals in terms of that of a freshly set up mercury column. It was further agreed that these resolutions be communicated to the Electrical Standards Committee of the Board of Trade. It was agreed that the number 0·001118 should be adopted as the number of grammes of silver deposited per second from a neutral solution of nitrate of silver by a current of one ampere, and that the electromotive force of a Clark cell at 15°C. should be taken as 1·434 volts.

Prof. von Helmholz remarked that a column of mercury was much preferable to alloys, in which small fissures might exist or come into existence. He alluded also to the manner in which the difficulties of setting up such a mercury column, arising from the want of proper contact between the mercury and the glass, may be overcome. The British and German tests agreed so closely as to show that the results might be used for commercial purposes, possibly for centuries; though, for scientific purposes, some change might be needed. He and others had been sent here by their Government with the object of coming to an agreement on this subject with Great Britain, and it was hoped that America and France would also adopt the resolutions.

Wire Standards of Electric Resistance, by Dr. Lindeck, of Berlin.—The author described experiments on this subject. Alloys containing manganese seem to be the best for the purpose. Those containing zinc are the most objectionable because of impurities. Changes of resistance depending on the process of winding the coils were also investigated. The best results were got with the alloy manganin. Changes of resistance, apparently due to oxidation from contact with the air, take place; but these can be avoided by varnishing the wire. The resistance rises slowly with temperature, reaches a maximum, and then decreases rapidly.

Prof. Sylvanus Thomson said that, in working with manganin, he had found that it could not be relied upon if too strong a current were sent through it. He agreed that no alloy containing zinc should be used.

On the Clark Cell, by Dr. Kahle, Berlin.—Dr. Kahle gave details of experiments made on Clark cells. He found that they furnished a very trustworthy standard of electromotive force, and that they were very suitable for practical work.

Prof. Carhart said that he had found cells, made by different persons at different times, gave practically the same result when used under the same conditions.

Mr. Glazebrook said that he had come to the conclusion that differences amongst the results given by different cells were due to the fact that the time taken to reach the equilibrium condition differed in different cells.

Preliminary Account of Oceanic Circulation, based on the Challenger Observations, by Dr. A. Buchan.—In communicating this account, Dr. Buchan remarked that the enquiry had so far advanced that the chief results could be stated. The *Challenger* observations have been supplemented by those of Mohn, Agassiz, J. T. Buchanan, Belknapp, and Capt. Wharton. The surface winds of the globe have a special bearing on the subject of ocean temperature. The surface winds of the Atlantic generate currents which have the effect of raising the temperature on the west side of the Atlantic, at depths from 100 to 500 fathoms, about 10 degrees above the temperature at these depths on the east side. At 500 fathoms the temperature is nearly the same at both sides of the Atlantic, but at lower depths the effects are reversed. At these depths the west side is more under the influence of the Arctic currents along the American coast, and the east side is more under the influence of the under currents from the Mediterranean and the equatorial regions of the Atlantic. This high temperature distribution extends northwards even beyond the Wyville Thomson ridge between Shetland and Iceland. At 700 fathoms the temperature just south of this ridge is five or six degrees higher than it is over the Pacific, Indian, and

South Atlantic Oceans at that depth. At 200 fathoms the temperature of the Mediterranean is about 56°, and is practically constant down to the bottom (1500 fathoms in some places). Similar conditions hold in the Gulf of Mexico, where the temperature at 700 fathoms is $25^{\circ}\cdot 5$, with no change at lower depths. On the other hand, north of the Wyville Thomson ridge in the North Atlantic, there is a uniform temperature of about $29^{\circ}\cdot 5$ at all depths below 700 fathoms—that temperature being about two or three degrees higher than the freezing point of the water. This undercurrent of warm salt water from the Mediterranean, extending even beyond the North Cape of Norway, seems to explain why there is no instance of an iceberg appearing off the west coast of Europe.

Physical Condition of the Waters of the English Channel, by Mr. H. V. Dickson.—The constitution of the samples of water agreed, on the whole, with that of the *Challenger* samples, coinciding entirely with that of the Atlantic water. The tidal currents are sufficiently strong to keep the water thoroughly mixed from the top to the bottom, except off Start Bay, where a vortex is formed—the water being colder in summer, and warmer in winter, than the surrounding water, and this spot is one of the best fishing grounds in the Channel.

On Primary and Secondary Cells in which the Electrolyte is a Gas, by Prof. Schuster.—When an electric discharge passes through a part of the gas filling a tube, all the gas is brought into a state in which it readily conducts electricity. Prof. Schuster has studied the laws of this conduction. If we assume that the primary phenomena of discharge depend on dissociation of the molecules, he remarked that it must often have appeared peculiar to experimenters that no phenomena of polarization appear. When an elementary gas is used no such phenomena appear. When compound gases are used only slight polarization appears; but Prof. Schuster has found that the phenomena become very marked when hydrocarbons are used. The law of decrease of polarization in this case resembles that which is observed when liquid electrolytes are used. This points to the performance of work of the nature of electrolysis. The magnitude of the effect depends on the nature of the electrodes. It is small when copper and iron are used; but is very large when aluminium or magnesium are used. When a latter metal was employed, a direct current being passed for a long time, a reverse electromotive force of 35 volts was got from a single cell. This shows that the action is similar to that of a secondary cell. Prof. Reinold has already described cases in which gases act as an electrolyte in a primary circuit when under the influence of a discharge. Prof. Schuster has found that, in such cases, the employment of aluminium electrodes gives very strong effects.

On Leaky Magnetic Circuits, by Dr. du Bois.—It appears from the experiments described that the leakage decreases when the magnetization is increased.

Experiments on the Electric Resistance of Metallic Powders, by Dr. Dawson Turner.—It is well known that metallic powders have very great electric resistance. This can be reduced to an extraordinary degree by the passage of an electric spark in their neighbourhood. Amongst other substances Dr. Turner has tried powdered aluminium, copper, annealed selenium, iron filings, small shot, mixtures of aluminium and resin fused into a solid mass, etc. The best results were obtained with the first two. A short glass tube, filled with powdered aluminium, is placed in circuit with one or two cells and a galvanometer. No current passes until a spark discharge occurs in the neighbourhood, when a fairly large effect becomes visible. The powder continues to conduct for a short time unless it be shaken or disturbed, when the effect ceases. In the case of the rod of aluminium and resin, mere shaking does not destroy the effect, though the application of heat does. When the resistance has once been lowered in this way, the powder becomes very sensitive, a spark at a great distance produces the effect, and a very slight jar destroys it.

On the Stability of Periodic Motions, by Lord Kelvin.—The mathematical investigation of this subject was illustrated by an experiment in which a simple harmonic vertical motion was given to the point of support of a pendulum. When the period of the superposed motion was one half of that of the natural motion of the pendulum, the equilibrium became unstable, and the slightest disturbance caused the vertical motion of the bob to be changed into transverse motion of increasing amplitude. If the superposed period were now lessened, the vertical motion again became stable. Similarly a rod poised vertically in unstable equilibrium could become stable by having its point of support moved with simple harmonic motion, of proper period, in a vertical line.

Prof. Osborne Reynolds remarked that it was well known to practical engineers that a revolving shaft, when driven at a certain speed, began to bend, and might even break, though at higher speeds it would again become straight. Lord Kelvin had now explained this effect.

On the Specific Conductivity of Thin Films, by Profs. Reinold and Rücker.—When the film was an aqueous soap solution containing a considerable portion of glycerine and a small proportion of a metallic salt, the specific conductivity was the same, whether the liquid was in mass or was drawn out into a film not exceeding 1-200,000 in. in thickness. When the liquid consisted of an aqueous soap solution alone, the specific conductivity increased when the thickness became small, until, in the thinnest film observed, it was seven times as great as at first. The effect seemed to be due to a breaking down of equilibrium when the tenuity was extreme.

A Contribution to the Theory of the perfect Influence Machines, by J. Gray, B.Sc.—The theory of the perfect influence machine has been shown by Clerk Maxwell to be analogous to Carnot's theory of the perfect heat-engine. Maxwell points out that there is a loss of energy in the ordinary influence machine through sparking at the contacts, which would render the machine inefficient, even though losses from leakage and the like were done away with. Maxwell has described a machine in which sparking and the loss due to it is eliminated. This is done by causing the carrier of electricity always to make contact with charging and discharging conductors when the former is at the same potential as the latter. In the case of the discharging conductor, this is done by prolonging the contact springs to meet the carrier; in the case of the charging conductors this is not sufficient; it is necessary to surround the ends of their contact springs by two additional conductors charged to an equal and opposite potential, and of such capacity as will just reduce to zero the potential of the small quantity of electricity left from the previous discharge. These additional conductors were called by Maxwell regenerators, as being analogous to regenerators in the heat-engine.

The object of the author is to investigate the efficiency of an influence machine constructed according to Maxwell's design, and other designs less perfect. This is done by drawing a QV (quantity-potential) energy diagram for one revolution of the carrier. The results obtained are as follows:—

	Theoretical efficiency.
Maxwell's machine	1
,, ,, without regenerators	$\frac{Q}{Q+\frac{1}{2}av}$
,, ,, without long contacts on receivers	$\frac{2}{3}$
,, ,, without regenerators and without long contacts on chargers	$\frac{Q}{Q+\frac{1}{2}aV}$

where Q = quantity received or discharged by a carrier in each revolution,
V = the potential (numerical value) of the positive or negative receiver,
v = the potential of the residual charge to be reduced to zero by the regenerator,
a = the part of the carrier's capacity due to its not being completely surrounded by the discharging conductor.

The conclusion is that the regenerators are of much less importance than the long contacts in adding to the efficiency of an influence machine.

Experiments with a Ruhmkorff Coil, by Messrs. Magnus Maclean and A. Galt.—The quantity of electricity induced in a secondary circuit by a make in a primary circuit is equal to the quantity induced in the same secondary by a break in the primary. If, however, there is a non-metallic gap in the circuit, the *break* impulse causes a flow in one direction, and the *make* causes either no flow, or a much less flow in the opposite direction; because the short intense impulse of the former breaks down the resistance, while the comparatively long and less intense impulse of the make either does not break down the resistance at all or only does so to a slight extent, so that the effective resistance is much greater in one direction than in the other. To obtain the average difference of the quantity of electricity set in motion in one direction over that in the other, an electrolytic cell and a vacuum tube were placed in the secondary circuit of a small Ruhmkorff coil. The solution in the cell was sulphate of copper of density 1·7 with $\frac{1}{2}$ per cent. of commercial sulphuric acid added. The mean of seven experiments, lasting from two to four hours, gave the average electrolytic current, calculated from the gain of the cathode, as $\frac{1}{6}$ of a milliampere. A similar experiment, in which the vacuum tube was replaced by a very large liquid resistance, led to no result.

The Application of Interference Methods to Spectroscopic Measurement, by Prof. A. Michelson.—Prof. Michelson's "wave-compiler" consists essentially of a small plane sheet of glass with parallel surfaces and two mirrors. The mirrors are set at right angles to each other and the central plane of the glass passes through their line of intersection, making an angle of 45° with each of them. Rays of light from the source under examination fall upon the glass surface at an angle of 45°, and are partly reflected, partly transmitted, so as to suffer normal reflection at the mirrors, and finally proceed from the other surface of the glass, at an angle of 45°, to the eye. Normal displacement of one of the mirrors parallel to itself causes a difference of path which produces interference. If the source of light emits radiation of two wave-lengths (as in the case of incandescent sodium), or of more, the brightness of the interference bands—regarded from the centre outwards—exhibits periodic variation, which can be accurately observed. The law of variation can be calculated when the distribution of light in the source, as regards wave-length and intensity, is known. Conversely, the method can be used to determine the nature of this distribution. Mr. Michelson has examined various sources of light—oxygen, hydrogen, zinc, cadmium, mercury, &c.—and has found that lines which in the most powerful spectroscope appear single, are really double, triple, or even more complex. In examining hydrogen at different pressures and temperatures the results indicated that the widths of the component lines decreased as the pressure decreased, but not without limit. Investigations made on a large number of substances give strong confirmation of the kinetic theory of gases.

On a Periodic Effect which the Size of Bubbles has on their Speed of Ascent in Vertical Tubes containing Liquid, by Dr. F. T. Trouton.—The chief peculiarity observed when a bubble of air ascends in water is that the speed of ascent is a periodic function of the size of a bubble. The form of the curve obtained by plotting the volumes of the bubbles as abscissæ and the corresponding speeds as ordinates showed that at first, as would be expected, increase in size diminishes the speed; but afterwards the speed increases in value, then reaches a maximum at about twice the minimum speed; and so on two or three times, depending on the diameter of the tube employed. The oscillations in the curve die out in much the same fashion as those of a pendulum in a viscous medium. The form of the bubbles was almost spherical at the first minimum; after this the bubble is pointed at the top until the second minimum is reached, when it is again rounded at the top, but has a dumb-bell shape, and so on, presenting in this way similarities to the breaking up of a liquid column through surface tension. Liquids which do not mix with water were used instead of air; and air bubbles in other liquids were also used.

On a Method of Determining Thermal Conductivities, by Mr. C. H. Lees.—The method has more direct application to the determination of the conductivity of a liquid than previous methods have. It consists in measuring the amount of heat conducted, under given conditions, through a film of liquid placed between two copper cylinders. It was found most convenient to keep the upper cylinder at the temperature of the surrounding air, while the lower one was kept cool by water from the mains. Precautions were taken against errors from radiation, &c.

A Magnetic Curve Tracer, by Prof. Ewing.—The apparatus is designed to plot mechanically the ordinary magnetization curve. The curve is traced on a screen by a spot of light reflected from a mirror, which is subjected to two motions—one proportional to the magnetizing force, the other to the magnetization. These motions are communicated by means of the sagging of wires placed in air-gaps in magnetic circuits. In the one case, the wire carries a steady current in a varying field; in the other the wire carries the varying current in a steady field. The curves may be traced on sensitized paper; and the instrument should be of much use to engineers for testing purposes. In working with the instrument Prof. Ewing has observed true effects of magnetic time-lag in the inward penetration of magnetization.

On a Magnetic Balance, and its Practical Use, by Prof. du Bois.—A test bar of standard size is placed within a magnetizing coil. Over this is placed an iron yoke, balanced on a knife edge, and having attached to it a graduated scale with sliding weights. When a current passes through the coil the equilibrium is disturbed, and it is restored by sliding the weight along the scale. The position of the weight then gives the magnetization in absolute measures in c.g.s. units. The position of the yoke is one of unstable magnetic and mechanical equilibrium.

On Earth Current Storms in 1892, by Mr. W. H. Preece.—In communicating this paper, Mr. Preece spoke of the great importance of observers at all parts of the globe contriving to collect data regarding electric storms.

On the Dielectric of Condensers, by Mr. W. H. Preece.—The author pointed out that in the condensers used by him there was evidence of work done upon the insulating material, which necessarily retarded the rate of propagation of signals.

On Polarizing Gratings, by Prof. du Bois.—The author has constructed minute gratings with silver wire scarcely visible to the naked eye. Radiant heat and long light waves are polarized by these gratings in the same way as electromagnetic radiations are polarized by larger wire gratings.

The Volume Effects of Magnetism, by Dr. C. G. Knott.—The results for iron tubes have been already described in NATURE. In one case a steel tube, of given bore and thickness of wall, gave increase of internal volume in all fields used. Usually the volume diminishes in low fields and increases in high. The effects were shown to the audience by projection upon a screen.

An Estimate of the Rate of Propagation of Magnetization in Iron, by Prof. Fitzgerald.—Assuming that the iron is constituted of a system of little magnets, and with possible assumptions as to the size of these magnets and their strength, it is found that their natural rate of vibration may be one hundred millions per second. Unless the period of the vibration propagated through the iron approximates to this the wave lengths would be very small; while quicker vibrations, with periods like those of light, would not be propagated at all.

Experimental Proof that the Coefficient of Absorption is not affected by Density of Illumination, by Dr. W. Peddie.—When parallel rays of light pass through a uniform absorbing medium, the intensity of the light diminishes according to a certain law. The assumption which, on this point, is made the basis of the theory of radiation is that the fractional dimunition of intensity, at any stage, per unit of thickness traversed (called the coefficient of absorption), is independent of the intensity of the light. Sir G. Stokes has indicated a method of testing the point by the reflection of light, at nearly perpendicular incidence, from the surface of glass—part of the absorbing medium being placed in the path of half of the light before reflection, and a similar part being placed in the path of the other half after reflection. Both portions, being then projected on a screen, could be directly compared in respect of colour and intensity. No test seems to have been made by this or any other method. In Dr. Peddie's method light is passed through two double image prisms and a plate of quartz. Four rays are thus produced, coloured alike in pairs, the colour of one pair being complementary to that of the other. The colour of one pair can be made to match as nearly as possible the colour most readily absorbed by the medium, similar portions of which are placed at different distances from the points from which these rays are made to diverge by means of a lens. The light being projected on a screen, a direct comparison is obtained. The media used were pieces of surface-coloured glass. In no case was any difference observed, although the intensity varied from 1 to 1000, and the eye could have observed the difference of one per cent. in the brightness of the two discs thrown on the screen, without the additional help of change of colour.

On Dispersion in Double Refraction due to Electric Stress, by Dr. John Kerr.—The fact of dispersion has been established, and it is found that the optical effect depends upon the wave-length, being the inverse ratio of the square root of the wave-length.

On a Delicate Calorimeter, by Messrs. J. A. Harker and P. J. Hartog. This is essentially a Bunsen ice-calorimeter, with solid acetic acid instead of ice, so being much more delicate, and capable of being used at ordinary temperatures.

On Graphic Solutions of Dynamical Problems, by Lord Kelvin.—The method of drawing meridional curves of capillary surfaces of revolution, described in "Popular Lectures and Addresses," vol. i., 2nd edition, pp. 31-42, suggests a corresponding method for the solution of dynamical problems.

Reduction of every problem of Two Freedoms in Conservative Dynamics, to the drawing of Geodetic Lines on a Surface of given Specific Curvature, by Lord Kelvin.

1. Any conservative case of two-freedom motion is proved to be reducible to a corresponding case of the motion of a material point in a plane.

2. In plane conservative dynamics, with any given value for the energy-constant, E, the resultant velocity, q, at any point (x, y) is a known function of (x, y), being given by the equation

$$q^2 = 2(E - V) \quad . \quad . \quad . \quad . \quad (1)$$

where V denotes the potential at (x, y); and every problem depends on drawing lines for which $\int q\,ds$ (the Maupertius "action") is a minimum.

3. Considering any part, S, of the infinite plane, find a surface, S', such that any infinitesimal triangle $A'B'C'$ drawn on it has its sides q/q_0 of those of a corresponding triangle ABC in the field, S, of our plane problem; q_0 denoting the value of q at any particular point (x_0, y_0) in the plane. By the principle of least action we see instantly that the lines on S' corresponding to paths on S, are geodetic. Thus the *adynamic* case of motion of a particle on S', is found as a perfect and complete representative of the motion on the plane surface S, under force with any arbitrarily given function V, for its potential, and any particular given value, E, for the total energy of the moving particle.

4. It is easily proved that the surface S', to be found according to §3, exists; and that its specific curvature (Gauss's name for the product of its two principal curvatures) at any point; is equal to

$$\frac{q^2{}_0\,\Delta^2 \log q.}{q^2}$$

5. Examples are given of the finding of S'. As one example, illustrating the practical usefulness of this method in dynamics, the problem of the parabolic motion of an unresisted projectile is reduced to the drawing of geodetic lines on a certain figure of revolution of which the explicit equation is expressed in terms of elliptic functions.

THE PERIODIC VARIATIONS OF ALPINE GLACIERS.

THIS twelfth Report, dealing with the Alpine glaciers and their changes, by Dr. Forel, comes in the nick of time, and will be generally welcomed, for it announces that the question of glacier-changes in the Alps will in future be studied systematically; and, further, we learn in a postscript that the State Council of the Canton of Le Valais have, on the proposition of M. Maurice de la Pierre, head of the Home Department, decided to take under its efficient direction the studies of observation and control of the variations of glaciers. These observations are confided to the charge of the Cantonal Administration of Forests, the head of which is M. Antoine de Torrenté at Sion. M. Forel records this act of intelligent and prudent administration with keen satisfaction and true gratitude, and would gladly see it imitated by other cantons possessing glaciers. M. Forel publishes also the report, which, in compliance with the wishes of M. de la Pierre, he had addressed to the Home Department of Le Valais. It is equally applicable to the glaciers of other cantons in Switzerland, and we therefore print it *in extenso*.

M. de la Pierre, Councillor of State, head of the Home Department, Sion.

SIR,—Referring to the interview you granted me on January 31, and in reply to your question, I have the honour to give you the following particulars:—

Glaciers in general, and particularly those of Le Valais, are subject to variations in shape, which, according to an irregular periodicity, cause them sometimes to grow in length, in breadth, in thickness, sometimes to decrease, often in very considerable proportions. These variations, which in recent centuries have attracted the attention of the populations interested and of naturalists, have in this century been the subject of direct study, especially during the last twenty years.

It has been recognized that most of the great catastrophes which have ravaged the region of the high Alps, have been caused by these glacial variations. It is when the glacier extends, lengthens, arrives at its maximum, that it not only invades the fields and destroys Alpine chalets, but barricades the valleys, arrests the flow of rivers, and creates temporary lakes, the evacuation of which ravages the country; or else, surpassing its usual dimensions, it forms an avalanche, the destructive power of which is terrible. Taking my examples from Le Valais, I attribute to forces of this kind: the catastrophes of the Valley of Saas, 1633, 1680, 1772, caused by the overflow of the lake Mattmarck, due to the stoppage of the Viège by the glacier of Allalin; the catastrophes of the valley of Bagne, 1545, 1605, 1818, caused by the formation of a temporary lake behind the barricades of the glacier of Giétroz; the catastrophes of Randa, 1636, 1819, caused by the fall of the glacier of Bies, which had assumed extraordinary dimensions; perhaps we might also attribute to the same source the inundations of St. Bartholomew, 1560, 1635, 1636, 1835, which may have been due to the excessive increase and fall of the terminal extremity of the glacier of Plan-névé of La Dent-du-Midi.

Since these variations of glaciers are the cause of great catastrophes in mountainous regions, they are deserving of attentive study; there is scope to form theories and to recognize the rhythm of their periodicity; it is very necessary to be able to foresee their development, in order to ward off threatening events.

Now, the preparatory study which we have made within the last few years has shown us that the periodicity of glacial variations is much longer than was formerly believed to be the case; the popular dictum that the increase in the size of glaciers recurs every seven years is certainly incorrect. We cannot yet give definite figures, but probably the cycle of glacial variation is as much as 35 to 50 years. The latter period alone has been studied attentively; if 1850 or 1855 be fixed upon as the epoch of maximum of glaciers, they have been steadily decreasing in past years, so that from 1870 to 1875 we were not aware of a single one on the increase. In 1875 the Glacier des Bossons du Mont Blanc gave the signal for a new period by commencing to lengthen out; it was followed in 1878 and 1879 by the glaciers of Trient and Zigiorenove, then successively by some thirty glaciers in different valleys of Le Valais; but the phase of increase is not yet general in your canton; a number of large glaciers, Arolla, Otemma, Corbassière, Le Gorner, Le Rhone, are still decreasing or stationary. It is only of the Mont Blanc group that the increase can be said to be general; in Le Valais it is in process of development, and we are still very far from the maximum stage of glaciers. If, as is probable, the maximum only arrives at the commencement of next century, the actual period of glaciers will have lasted more than fifty years.

Thus this is a phenomenon, whose cycle is equal or superior to that of the average human life; one generation of men witnesses only one of the glacial variations. It is a phenomenon of such majestic slowness that its study is exceptionally difficult.

A phenomenon of which a man can, in his whole life, see but one manifestation, surpasses in its amplitude the powers of initiative individual study. To observe the facts of so prolonged a period, organizations are required of a superior duration. Shall we address ourselves, therefore, to learned societies, which, being continually renewed, may be supposed to have sufficient continuance? We fear that, even in the most powerful of these societies, Societies of Naturalists and the Alpine Clubs, a sufficiently keen interest in observations, which can only be utilized after the lapse of some generations will not be felt for the observations to be organized and carried out with the necessary perseverance. It seems to us that the State alone, by virtue of the indefinite continuance it enjoys, is in a position to follow out this study with a sufficiently long grasp. However much we may be in favour of private individual or collective initiative action in researches and scientific work, in this special case we believe it advisable to have recourse to the State administration, considering it the only institution of sufficient duration to proceed to the study of phenomena of such extreme slowness.

We therefore take the liberty of addressing ourselves very respectfully to the Government of the Canton of Le Valais, and begging it to introduce the study and observation of the variations of glaciers, which have so great an influence on the prosperity of mountain populations.

It seems to us that the State department best fitted for such a study would be that of the Administration of Forests. The forest inspectors and their agents are called upon by their functions to travel over the high valleys of the Alps; they would thus be able, without great additional labour, to undertake the observation of glaciers.

As to the programme on which they should work, we would simplify it as much as possible, and reduce it to two points:—

1. To attentively survey the glaciers in order to fix for each one the year of maximum and the year of minimum extent in their successive variations.

2. To specially watch the dangerous glaciers, and warn the Administration of the danger they may cause by assuming exaggerated dimensions during their phase of development.

In order to carry out this double programme, the Government should charge each inspector of forests to study the glaciers of his district, and to inscribe on a register *ad hoc* the state of growth and decline of each glacier every year. For important glaciers, interesting or dangerous, he should have measurements made from fixed marks, and state in exact figures the changes in the dimensions of the glaciers; for little, uninteresting, or unimportant glaciers, occasional inspection and the reports of the mountaineers would suffice to ascertain their state of growth or decrease.

M. Antoine de Torrent, Inspector-General of the Forests of Le Valais, has long been occupied in collecting observations on the glacial variations of our Alps; it is from him that we have obtained all the facts recorded by science in this field of research in Le Valais; it is for him, not for us, to give instructions as to the way in which the observations should be organized.

This study is not an expensive one; it calls for no great outlay on the part of the State, nor does it make great demands on the powers and the time of the observers. It may lead to important and useful results. It can only be successfully carried out by the State, since that alone has the necessary persistence to continue it long enough. I therefore venture to recommend these studies on the variation of glaciers to your great benevolence, and to the enlightened solicitude with which you follow all questions interesting to the public welfare. Men of science, who consecrate their lives to the study of the phenomena of nature, are ready to help you to the best of their ability to study these questions from a theoretic point of view. But it is necessary, in order to arrive at practical results, to have a collection of materials of observation which the State alone seems to us capable of bringing together with success.

Accept, M. le Conseilleur de Etat, the expression of my very respectful and devoted consideration.

F. A. FOREL.

Morges, February 10, 1892.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, August 8.—M. de Lacaze-Duthiers in the chair.—The "Pythonomorphs of France," by M. Albert Gaudry. Announcing the discovery of the snout of one of the great chalk reptiles termed pythonomorphs by M. Cope, on account of their similarity to the sea serpent as imagined by the ancients. The specimen is from a pythonomorph 10m. long, and was found in the upper chalk of Cardesse, near Pau. It is similar to the *Mosasaurus giganteus* of Maestricht, and has been termed *Liodon mosasauroides*. A smaller and somewhat similar specimen was also found, and was termed *Liodon compressidens*. These and a few minor fragments are the first representatives of the pythonomorphs found in France.—On the production of sugar in the blood at the expense of the peptones, by M. R. Lépine.—On the lava of July 12, 1892, in the torrents of Bionnasay and Bon-Nant (catastrophe of Saint-Gervais, Haute Savoie), by M. P. Demontzey. After describing the probable course of the catastrophe, the writer comes to the following general conclusion:—That the lava of July 12 has behaved exactly like those which have been observed before in the torrents of the Alps and the Pyrenees. That its energy was all the more disastrous as the transport in masses commenced in the most elevated regions of the torrent basin after the sudden bursting forth of a large body of water concentrated more rapidly even than in the most violent hailstorms in the upper basins of torrents without glaciers. That the volume of the deposited materials of all sorts—estimated at about one million cubic metres—presents no anomaly in comparison with the relatively small amount of water, which effected the transport by a series of successive bounds, with alternate momentary accelerations and retardations of speed. That this torrent phenomenon has substituted for a simple and hitherto harmless rivulet a torrent whose activity can be mastered with a relatively short delay. That both in the Alps and the Pyrenees similar cases of the transformation of peaceful rivulets into formidable torrents can be cited, aggravated by the fact of their being caused by rain, which is even more difficult to predict and ward off than the dangers presented by a glacier. And lastly, that this great disaster could not have been provided against, since nobody had had the idea even of exploring the glacier of Tête-Rousse.—On a property of lamellar bimetallic conductors submitted to electromagnetic induction, by MM. Ch. Reignier and Gabriel Parrot. An arrangement recalling Faraday's disc is obtained by substituting for the ordinary copper conductors thin plates composed, along their thickness, of a very magnetic and a highly conducting metal, so placed that the lines of force are perpendicular to their thickness. The flow of induction emanating from the north pole is divided into several sheets of parallel lines very close together, which only traverse the magnetic portions of the bimetallic conductors, and the tubes of force become cylindrical. The available energy in such an arrangement increases at a rate which is sensibly proportioned to the height of the conductors. An apparatus constructed on this principle gave, with a weight of 750 kg. and a velocity of 500 revolutions, 32,000 watts giving an output of 42 watts per kg. of the machine.—The application of the measurement of density to the determination of the atomic weight of oxygen, by M. A. Leduc. The composition of water by volume, and thence its composition by weight, were determined by finding the density of a mixture of hydrogen and oxygen produced by the electrolysis of an alkaline solution. After an electrolysis of several days, during which the superfluous gas was allowed to escape through mercury, the liquid and the platinum poles were saturated with gas, and the density obtained by the method previously described did not vary by more than 0·0001 gr. The value within $\frac{1}{100}$ per cent. was 0·41423. The volume ratio between hydrogen and oxygen was 2·0037 at 0°, and the atomic volume of oxygen 1·9963. The atomic weight of oxygen by this method is 15·877, and by the synthetic method 15·882, so that 15·88 must be taken for the mean atomic weight. Hence the molecular weight of water vapour is 17·88, and its theoretical density 0·622.—On the general form of boiling-point curves for central substitution compounds, by M. G. Hinrichs.—Note on the existence in the earth of an acid mineral substance as yet undetermined, by M. Paul de Mondesir. If all the carbonic acid contained in lime be driven off by a strong acid, and the ratio of lime to carbonic acid be carefully measured, the lime is found to exceed the quantity necessary for saturation. The earth remains always acid and capable of decomposing carbonate of lime in the cold. That this acid residuum cannot be humic acid or free silica is proved by the total destruction of the organic substances by ignition or potassium permanganate, which leaves the property in question unaffected. The quantity of acid matter varies from ·2 to 1 per cent. of the earth. It is very stable, and its composition has not yet been determined.—Calcareous soap and boiler explosions, by M. A. Vivien.—Pupine, a new animal substance, by M. A. B. Griffiths. This is extracted from the skin of the chrysalis of several lepidoptera.—On the colouring matter of *Micrococcus prodigiosus*, by the same.—On the coccoid state of a nostoc, by M. C. Sauvageau.—On an alga living in the roots of the *Cycadeæ*, by M. P. Hariot.—On the presence of fossils in the azoic formations of Bretagne, by M. Charles Barrois.—On the discovery of cut flints in the quaternary *Rhinoceros Mercki* alluvium of the Saône valley at Villefranche, by M. Ch. Depéret.

ROME.

R. Accademia dei Lincei, June 5.—The 289th annual meeting, honoured by the presence of H. M. King Umberto I.—The President introduced the two committees charged with the examination of the works in competition for the two royal prizes of 10,000 lire each, one for social and economic sciences, the other for mathematical sciences. Senator Lampertico, reporting for the first committee, said that, although two essays, one on "Ancient Socialism," by Salvatore Cognetti de Martiis, and another on the laws of the distribution of wealth, bearing the motto, "Laboremus," had shown considerable merit, the committee had not felt justified in awarding the prize to either.

Professor Cerruti, on behalf of the second committee, reported that two candidates had been found equally deserving of the mathematical prize, viz., Professor Luigi Bianchi by his essays on the triple orthogonal systems of Weingarten and allied subjects, and Professor Salvatore Pincherle in virtue of his various works on the general theory of functions. It was therefore decided to divide the prize equally among these two candidates. —The last of the ministerial prizes for professors of secondary classical and technical schools, amounting to a total of 9000 lire for philological, and 9000 lire for physical and chemical subjects, were distributed among thirteen candidates, prizes of 3000 lire being obtained by Professors Nasini and Costa for their work "On the Variation of Refractive and Dispersive Power of Sulphur in its Compounds," and by Dr. Enrico Salvioni for his contribution "On the Construction of the Legal Ohm."—General Ferrero then addressed the meeting on the subject of scientific measuring instruments. Although, he said, the human eye, that natural model of the telescope, the microscope, and the photographic camera, can distinguish within a few hundredths of a millimetre whether two points are in contact; although the ear can appreciate sounds ranging from 32 to 70,000 vibrations per second, and is able, while following the rhythm of a full orchestra, to discover the slightest dissonance; yet the power of our senses is limited to a comparatively small portion of the infinite variety of external phenomena, that portion which is of more immediate value for our merely animal life. The errors which the unaided senses are liable to lead us into are mainly due to their subjectivity, which renders the impressions of one individual incomparable with those of another, or with his own under different conditions. The use of instruments enables us to submit these impressions to measurement, to compare them amongst themselves, and immensely to extend our field of investigation towards the infinitely great and the infinitely small. The progress made in this direction during the last few hundred years justifies the hope that the time is not far distant when the results of observation will be as far as possible beyond the personal influence of the observer. The disciple of science will read the truth in the book of nature, traced out by the phenomena themselves. The universe, which has always remained inaccessible to metaphysics, will willingly disclose its secrets to the researches of modern science. This owes its great progress during the last century mainly to the perfection and delicacy of its measuring instruments, which has made modern astronomical observations a thousand times more accurate than those of the Chaldees, and has, by making very minute differences of temperature appreciable and measurable, enabled biology to enter the ranks of the exact sciences. The accuracy of measurements of length and mass is ensured by the arrangements in connection with the International Office of Weights and Measures at Bréteuil. Some recent comparisons of standards gave a probable error in length of 1/20,000mm., while that for mass was 4/1000 mgr. The determination of weight has been carried to such a pitch of accuracy, that it has been found possible, at Bréteuil, at Monaco, and at Rome, to measure the slight differences of weight produced by varying the height above the ground by a few metres. For the measurement of time there has been no necessity of fixing a conventional standard. The marvellous invention of the pendulum has made it possible to subdivide almost indefinitely the natural fundamental unit, the duration of the rotation of the earth. In the determination of longitudes the error has been reduced to one or two hundredths of a second. Hipp's chronoscope, which may be called a microscope for time, enables the observer to subdivide time to a thousandth of a second. The impulse given to biological research by such instruments has been astonishing. The time of reaction to the various sensory stimuli has been fixed at 136 thousandths of a second for sound, at 150 for light, 133 for touch, 359 for taste, and 443 for smell, while the velocity of propagation of a nervous impulse has shown itself to be 37m. per second. In artillery, the chronoscope has been utilized for the study of the initial velocities of projectiles, and for the tracing of diagrams expressing the relations between spaces, times, and explosive pressures. Errors of observation may be due to the imperfection of the senses, to unavoidable faults in the construction of the instruments, and to external influences. These may be classified according as they are constant or accidental, or better as periodical or otherwise. Most of the errors due to the observer, and of those due to external influences, are periodical, and may be eliminated by repeating the observations under varying conditions. The calculus of probabilities shows that the precision of results, so far as the elimination of purely accidental errors is concerned, increases with the square root of the number of observations. But experience shows that beyond a certain number of observations the increase of precision is illusory. This is probably due to the existence of other errors of a constant character which escape analysis, and from which it is not possible to protect the observations. Experiment also proves that for all kinds of work the maximum error does not exceed a certain limit, which is a function of the mean error. For angular measurements, this does not exceed three times the mean error, so that according to Gauss's law of errors it would be safe to lay 1000 to 1 against the chance of an error greater than 3·2 times the mean error. The observer himself must above all have physical qualities enabling him to use his senses under the best possible conditions. In addition to well-trained senses and facility in managing his instrument, he must have a clear mind, a correct judgment, and a sound scientific preparation for the research he undertakes. Concentrated upon his research, he must abstract himself from the surroundings among which he lives, and possess a spirit unimpassioned enough to subject himself to a purely objective criticism. In concluding, the speaker pointed out that there is at present no science which treats of measurement in general, as a preparation to all the sciences which aim at quantitative results. Many treatises on astronomy, on geodesy, on physics are prefaced by theories of instruments and the compensation of errors. But even those works which profess to treat of the art of measuring are usually limited to geodetic and topographic measurements. It is to be hoped that this important vacancy may soon be filled up, and that a *Science of Measurement* will unite the elements dispersed among the various sciences in one compact and harmonious whole.

BRAMWELL'S CLINICAL ATLAS.

Atlas of Clinical Medicine. By Byrom Bramwell, M.D. Vol. I. (Edinburgh: Constable, 1892.)

THIS large and handsome volume is highly creditable to the author and to the Extramural School of Edinburgh, in which he is a lecturer. It consists of a series of thirty admirably coloured plates, mostly portraits of patients, with about an equal number of woodcuts, and descriptive letterpress. The account of the several diseases illustrated is so full and good that it almost makes the work a collection of illustrated monographs.

The diseases described and portrayed in this first volume are myxœdema and sporadic cretinism, Addison's disease, Hodgkin's disease, unilateral atrophy of the face, bulbar paralysis, Ophthalmoplegia externa, Molluscum fibrosum, Kaposi's disease, variola, melancholia, and mania.

There are also reports of cases of Friedreich's disease and of a few other rare morbid conditions.

The plan adopted by the author is to give a detailed account of the case or cases illustrated, and then a discussion of the disease under the heads of anatomy, diagnosis, and treatment, concluding with minute hints (such as one would give to intelligent ward-clerks) as to the points of clinical investigation. No order is observed in the sequence of subjects, and as the work is without a preface (though not, we are glad to say, without an index), it is not clear whether the author has formed any other plan than publishing interesting cases as they may come under his notice. The words "Volume I." on the title-page encourage the hope that Dr. Bramwell contemplates an additional series, and in that case it might be desirable to arrange the completed work in alphabetical or some other convenient order.

To take the first subject treated—Myxœdema—as a specimen.

There is first a brief notice of the first patient whose portrait is given; then an account of the original description of this remarkable disease by Sir William Gull in 1873; next a discussion of its geographical distribution and incidence on sex and age; the symptoms and pathology follow, and the author agrees with the conclusion of most who have studied the question, that this peculiar condition is in some way dependent on atrophy of the thyroid body; finally, the treatment is discussed, and the method of transplantation or grafting of a portion of the healthy thyroid of an animal into the patient's body is mentioned, with the results so far obtained by Bircher and Kocher.

Three portraits of patients afflicted with myxœdema follow, each with a full clinical history of the case. They are all three excellent, the colouring as well as the design being as good as chromo-lithography can produce.

This monograph is followed by one on sporadic cretinism, which Dr. Bramwell regards as "infantile myxœdema," another way of stating the true relation which Gull's remarkable insight led him to detect when he called the disease he discovered "a cretinoid condition in the adult." The paper is illustrated by seven uncoloured lithographs.

The two plates which belong to Addison's disease are the most artistic in the book; the difficulties are, of course, much less than in the case of myxœdema. Some of the other portraits are reproductions of photographs, very good in their way, but with the defects inseparable from this mode of illustration.

The three coloured plates of the singular affection described by Kaposi under the ill-chosen title of xeroderma pigmentosum are again excellent, particularly No. xviii. The illustrations of mental disease, although they display considerable power in draughtsmanship, are perhaps open to the objection of showing such fully developed and extreme aspects of the several states delineated, that they do not much help the recognition of less marked and typical examples.

We should, indeed, advise Dr. Bramwell, if, as we hope, he is encouraged to continue this valuable series of plates, to choose for illustration rather such infrequent morbid conditions as the diseases associated with the names of Graves, Addison, Raynaud, and Friedreich than the more familiar maladies which can be always studied at first hand.

It would also be well, perhaps, if in a scientific work of importance like this the catechetical method of instruction were omitted, which here and there interrupts the course of a paper. For instance, the following conversation, though no doubt an excellent paradigm of one method of class teaching, seems out of place where it stands (p. 30).

> *Dr. B.* (to the students). The case, gentlemen, is exactly what I suspected. It is, in fact, an absolutely typical example of the disease. . . . Such are the leading facts; I shall now be glad to hear any suggestions you may have to make as to the diagnosis.
> *A Student.* Tumour of the cerebellum.
> *Dr. B.* No, it is not a case of tumour of the cerebellum.

And so on.

Here and there an inelegant word or sentence strikes the eye. Thus Dr. Bramwell pertinently remarks that Addison's discovery was not merely "a happy hit," but spoils the phrase by adding "it was no mere fluke." A more important error of omission is, that in quoting the interesting quotation which follows from Addison's original work, Dr. Bramwell makes no clear distinction between the graphic and marvellously accurate account of idiopathic Anæmia, and the description of Melasma suprarenale, as the discoverer named it, which begins: "It was while seeking in vain to throw some additional light upon this form of anæmia that I stumbled upon the curious facts which it is my more immediate object to make known to the profession." The fact is that Addison, in a few pages, made known the existence and clinical features of *two* rare and remarkable diseases—idiopathic (since called grave or pernicious) anæmia and Melasma suprarenale (since called Morbus Addisonii). Dr. Bramwell is well aware of these facts, but it would have been useful if he had fully stated them, particularly as so much confusion on the subject still prevails both in this country and in Germany.

In conclusion, we must repeat that the present volume is most creditable to the author, to his artist, and to the publishers. It is remarkably moderate in price, and we trust that it will be so well supported by societies and private purchasers that Dr. Bramwell will be encouraged to continue so admirable an enterprise.

MODERN DEVELOPMENTS IN NORWAY.

Handbook for Travellers in Norway. Eighth Edition, Revised. (London: Murray, 1892.)

NORWAY now shares with Switzerland the privilege of being "the playground of Europe," and would even take precedence were it not for the sea voyage there and back. The recent progress of tourist invasion is curiously displayed by reference to the various editions of Murray's Handbooks.

We have before us the tattered remnants of our old travelling companion and oracle—Part I of the "Handbook for Northern Europe," including Denmark, Norway, and Sweden (1849). We are there told that by the last census in 1835 the population of Christiania was 33,000. The last edition tells us that its population is now 156,000. This is good progress for a capital city, but that of the chief town of Arctic Norway is still more remarkable. Tromsö (lat. 69° 38′ N.) had in 1816 only 300 inhabitants. Its present population is above 5,700, in spite of the fact that for more than two months the sun is continuously below the horizon. On the 22nd January, when it makes its first appearance over a crag to the south of the town, there is much jubilation, general holiday, and gun firing. In the old handbook the journey from Tromsö to the North Cape is described as an adventurous expedition demanding special preparations, which are described, and ladies are warned not to attempt it. Now it is as easy as a trip from London Bridge to Ramsgate, in steam packets incomparably superior to those which carry passengers down the Thames.

In the old handbook the Skjeggedalsfos, justly described in the present edition as "more grand and picturesque than any other waterfall in Europe," is unnoticed, as also in the next edition (1858). It was then unknown to the outer world, including Norway itself, until a solitary English pedestrian—the writer—ventured to explore the valley of the Tyssedal, to climb further on, and sojourn for a night in the Ringedal. It was first described in 1859 in "Through Norway with a Knapsack." Now it is one of the primary "lions" of Norway; there is a regular passenger boat on the lake, so solitary and desolate before 1859, professional guides, and an hotel in course of erection. The other grand region of Norway—the wildest of all—the *Jotunhjem*, which in the early editions of the Handbook was merely referred to in a single paragraph of a few lines, and in 1874 in two paragraphs bracketed as a side route, was made the subject of a special section of fifteen pages in the edition of 1880, illustrated by a special map of the district. This is continued in the present edition.

The Norwegian Tourist Club has strong claims upon the gratitude of all Norwegian tourists. Besides publishing in its transactions the record of explorations which have opened up many interesting districts, it has erected huts for refuge in the Jotunhjem, rendered a visit to the foot of the Vöringfos and many similar places possible, and set up many useful sign-boards indicating paths to waterfalls, points of view, &c. The assistance thus freely given to tourists in Norway contrasts very remarkably with the twopenny tricks of British landlords, who, for a consideration, permit their tenants to put up gates and charge admission to so many of our little dribbles designated waterfalls, and other natural objects of interest.

The present Handbook is brought up to date, and improved in many respects, notably by being printed on thinner paper than heretofore, and by setting the bye routes in smaller type, as Baedekker does. There is a valuable feature altogether new, viz., a Guide to Cycling Routes in Norway. The old accounts of the old hilly roads—which are now greatly improved or wholly superseded—led to false impressions on the subject. The writer delivered a lecture on "Cycling in Norway" to the Society of Cyclists some years ago which corrected these impressions, and induced many cyclists to do Norway; this appendix to Murray's Handbook will doubtless have still greater effect. In one important respect Norway offers the cyclist unrivalled advantages, viz., its admirable national organization of "Stations" for bed and board at regular intervals of about eight miles apart, and the annual publication of an authorized guide to all the roads and all the stations thereon, of which Mr. Bennett publishes an English translation with additions and maps, which render it a very valuable handbook.

An ideal handbook of Norway is, however, still demanded. The country being a narrow strip extending from 58° to 72° of latitude, it lends itself to a scheme of simple mapping, in horizontal strips of one degree each, which would require no cross folding. Each degree on the scale of Munck's map would occupy only the depth of one of Murray's pages. The scale of this map is sufficient for pedestrians, cyclists, and carriole tourists. With such a series of maps and a small key map, the only handbook reference demanded would be designation of latitude. In 1880 the writer constructed such a series from Munck, and suggested its adoption by the publishers, but the suggestion was not carried out. The development, or rather creation, of hotels in Norway is marvellous. The night before last we stopped at the Stalheim Hotel, dined in a magnificent salon, with roomy seats for 300 guests; music at dinner; concert in capacious smoking-room every evening; several drawing-rooms and 200 beds; all the salons lighted by electricity. Formerly—at the time of our first visit—the only provision here for travellers was a very inferior "station," a little hut with two or three questionable beds; no such luxury as white bread. Much of this is due to the modern development of cruising in what may be called cooperative yachts, such as the *Ceylon* and the larger vessels of the Orient Company and others, which carry about a hundred passengers on each cruise, visit the finest fjords, and halt for inland trips, thus rendering a short holiday available for Norway, so far as the outer fringe of its grand scenery is concerned. OUR BOOK SHELF.

Ostwald's Klassiker der Exacten Wissenschaften. (Leipzig: Verlag von Wilhelm Engelmann.)

IT is extremely important that every student of science should as far as possible make himself familiar with the history of discovery in the various subjects in which he is interested. He can hope to understand thoroughly the present position of any department of science only if he understands the stages of development through which it has passed. And by far the most effective way in which this knowledge can be attained is by the study of the memoirs in which the great masters of research have recorded their discoveries and described the methods by which their results have been reached. These documents bring the student into contact with the finest intellects which have been devoted to original inquiry; and he will be surprised to find how much freshness is often given to an old doctrine when it is apprehended precisely in the way in which it presented itself to the investigator by whom it was first brought to light. Judged from the point of view of later thinkers, the achievements of even the most illustrious workers belonging to past times may be in some ways found wanting; but the mistakes of great men, when properly understood, may sometimes be almost as instructive as those of their conclusions which have stood the test of the closest and most prolonged examination.

Important as it is that the classics of science should be widely and carefully studied, they have hitherto, unfortunately, been accessible only to a comparatively small class. It was therefore an excellent idea to issue a series of them in a convenient form and at a moderate price, so that they might be brought within easy reach of all to whom the study of science is either a duty or a source of interest and pleasure. Upon the whole, those who planned the present series may be congratulated upon the manner in which their scheme is being executed. Dr. W. Ostwald is acting as general editor, while particular departments have been entrusted to specialists—astronomy to Dr. Bruns, mathematics to Dr. Wangerin, crystallography to Dr. Groth, physiology to Dr. G. Bunge, the physiology of plants to Dr. W. Pfeffer, physics to Dr. A. von Oettingen. The only serious fault we have to find is that memoirs in foreign languages have not been printed in their original form, but have been translated into German. This cannot but diminish the usefulness of the series from an international or cosmopolitan point of view; and we may doubt whether it is really the best plan even for German students. So far, at least, as English and French memoirs are concerned, there are probably few serious students in Germany who would not have preferred to have before them the actual words used by the authors themselves.

The memoirs are not being issued in chronological order. The series opens with Helmholtz's paper on the conservation of energy (1847). This is followed by papers by Gauss, Dalton, Wollaston, Gay-Lussac, Galileo, Kant, T. de Saussure, Laplace, Huyghens, Woehler, Liebig, Bunsen, Pasteur, and many other famous men of scientific light and leading.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Aurora Borealis.

THE auroral display of Friday, the 12th inst., referred to in last week's issue of NATURE, would seem to have been visible over a wide area. Between 9.30 and 10 p.m. I observed it at Boppard, on the Rhine, a few miles above Coblence. The streamers were clearly defined, but presented no unusual features, being merely rays of whitish light which slowly dissolved as the moon rose above the crest of the range of hills running along the right bank of the river. On the previous evening I was at Strassburg where, owing, I suppose, to the gas and electric lights, I took the greyish appearance of the northern horizon to be nothing more than the usual light in that quarter at this season. Further south, in Switzerland and Austria, auroræ were seen on both nights. As to "the unusual time of year for such a display," I may mention that on Sunday, August 2, 1891, I witnessed a brilliant aurora from the Deck of the R.M.S. *Teutonic*, in latitude 48½° N., longitude 30° W. It varied considerably in intensity, and continued to do so for half an hour up to 10 p.m.

HY. HARRIES.

Bayswater, August 20.

An Unusual Sunset.

THIS evening (July 29th) we were treated to a sunset of rare type, one which is unique at least in the experience of the writer.

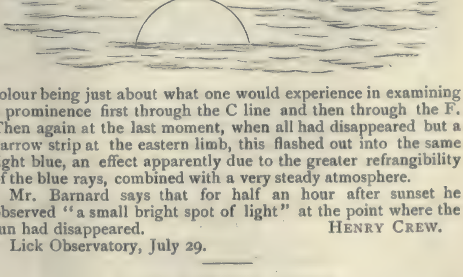
The fog was apparently *forming* round about the outer range of the mountains which lies between Mount Hamilton and the coast of the Pacific. Ordinarily, about this time of day, one can see the fog drifting over the tops of these mountains, and pouring into the valley on this side.

To-day, however, the crest of this range was barely visible above a sea of fog, which was unusually level and flat, as seen from above. Just over and along the crest was stretched a slender, thin, cloud which obscured the lower half of the sun's disc. Suddenly there formed underneath this semi-disc another of the same shape and size, and similarly placed, but not quite so bright as the true solar disc.

The accompanying figure shows essentially what was seen. The lower image I take to be that of the lower limb of the sun, shining down (from behind the upper strip of cloud) upon this quiet lake of fog and there reflected. But this amount of reflecting power in a fog if that be the true explanation, is very surprising, the image formed being not only bright and sharp, but very free from the usual glare of what are known as "brilliant" sunsets.

Another phenomenon, certainly not frequent in this country, showed itself on the limb of the sun at the point indicated by the dotted line A.

Here twice, just before the disc disappeared, the deep red colour of the solar surface turned to a bright blue, the change in colour being just about what one would experience in examining a prominence first through the C line and then through the F. Then again at the last moment, when all had disappeared but a narrow strip at the eastern limb, this flashed out into the same light blue, an effect apparently due to the greater refrangibility of the blue rays, combined with a very steady atmosphere.



Mr. Barnard says that for half an hour after sunset he observed "a small bright spot of light" at the point where the sun had disappeared.

HENRY CREW.

Lick Observatory, July 29.

The Red Spot on Jupiter.

ON August 19, at 14h. 40m., I began observing Jupiter with my 10-inch reflector, power 252. The red spot was seen slightly east of the central meridian, and it looked decidedly fainter and less definite than during the last opposition. The spot was estimated to be precisely central at 14h. 46m., and this is 14·3 minutes in advance of the time given in Mr. Marth's ephemeris (*Monthly Notices*, May, 1892). The motion of the spot has therefore shown a considerable acceleration during recent months. Between August 2, 1891, and February 2, 1892, the mean rotation period was 9h. 55m. 42·2s, but between February 2 and August 19, 1892, it was only 9h. 55m. 39·3s. This is a difference of 3 seconds, and it clearly proves that the motion of the spot is affected by some remarkable variations. A very decided retardation set in at the end of August, 1891, and continued to operate until February, 1892, but since that time the spot has exhibited an expected celerity of movement.

A large number of interesting details are now visible on the planet, but the bright equatorial spots which were so conspicuous about twelve years ago have virtually disappeared. During my observation on August 19 I saw the third satellite projected on the southern limb of the planet as a bright spot.

Bristol, August 20. W. F. DENNING.

Numbering the Hours of the Day.

WITH reference to Dr. Mill's recent interesting article on "Time Standards of Europe," I beg leave to emphatically take exception to the remark on p. 176, that "the system of numbering the hours of the day from 0 to 24 has failed to hold the popular fancy," as I maintain that the public has had no opportunity of testing the convenience of such a reckoning. The ordinary standard used in this country being railway time, so long as *Bradshaw* is printed on the old system of numbering the hours only up to 12, it is out of the question to expect the public to adopt any other. Any number of clock-faces numbered otherwise, either at Greenwich or all over the country, would not lead people to adopt the new system; the railway tables must first be altered, and as *Bradshaw* is compiled from the tables of separate companies, probably it would be necessary to approach the numerous railway companies with a view to their considering the subject and deciding upon a common plan. They would have to discuss not only the question of printing the time-tables on the new plan, but also whether it would be necessary, as well, to alter all the clock-faces at every station. I am given to understand that one railway company (in the Isle of Wight) for some time printed its tables—if it does not still—with the afternoon hours numbered from 12 to 23; though its example, because, I presume, it was of a small and uninfluential line, was not copied by any other company.

A further difficulty in the way of the public making any change is that the highest authoritative book on time matters—the *Nautical Almanac*, compiled and published by the British Government—still reckons the hours from noon. As a civil day commencing at noon is not suggested, would not the railway authorities have a ready objection to urge, and decline to alter their time-tables while time bearing the name of the national observatory, and used in the national ephemeris, were reckoned on a different plan from that which it is suggested they should adopt?

As regards the existing mode of reckoning time, the art of the printer is sometimes called in to show at once, without having to refer to the tops of columns or the sides of pages, which half of the day is meant; thus in the Midland Railway's, and part of the North-Eastern Railway's time-tables thick and thin type show this, and in some other tables a short vertical line appears between the figures of the hours and those of the minutes.

If the lists of places (p. 176) at which the time of the national standard is kept and not kept are intended to be complete, may I ask if Jersey has yet adopted Greenwich time? It had not up to 1887, although Guernsey had done so.

Sunderland, August 1. T. W. BACKHOUSE.

Propagation of Magnetic Impulses along a Bar of Iron.

IF at one end of an iron bar an alternating current be passed through a coil, will there be a wave propagation of magnetism along the bar?

Mr. Trouton (NATURE, vol. xlv., p. 42) hoped to find an answer to this question by searching after nodes, when two coils are placed one at each end of the bar, and the same alternating current is passed through both coils, or when one coil is employed on a closed iron ring. The search was conducted by a secondary coil connected with a telephone. Mr. Trouton found some places of minimum, but ascertained that these were not the nodes sought for.

Mr. Trowbridge (*Phil. Mag.* [5] 33, p. 374, 1892) made use of his phasemeter; two secondary coils, each connected with a telephone, could slide along the ring on which two large primary coils were placed. Two mirrors on the diaphragms of the telephones permitted to study change of phase by Lissajous's figures.

From his experiments, Mr. Trowbridge infers that there was no wave-motion along the iron ring; he believes that the propagation of magnetic disturbances produced by forced oscillations on iron bars is closely analogous to the propagation of heat over these bars.

Though I agree with Mr. Trowbridge in his conclusions, it seems to me that neither the experiments of Mr. Trouton nor those of Mr. Trowbridge could give any but embroiled results.

In collaboration with Mr. N. G. van Huffel, Phil. Nat. Cand. at this University, I have made some preliminary experiments on this question. Firstly, it became obvious that care must be taken against direct induction of the primary coils on the secondary. Only when the secondary coil which was connected with the telephone was embedded in a mass of copper everywhere 2·5 cm. deep, with a narrowly closing aperture for the iron bar, these direct effects were eliminated if the distance of the secondary from the primary coil were not too small. I have found no indication that similar precautions were taken in the quoted experiments.

But secondly, the telephone proved to be not the proper instrument for conducting the research. In most cases the variation of the magnetic intensity goes too slow to be perceptible by the telephone.

At one end of an iron bar (5 meters long, 1·5 cm. diameter), a primary coil A was placed; along the bar the secondary coil B (within a mass of copper, and connected with a telephone) could slide. A magnetic impulse was given by sending a current through A. If B were near A, a single tick was heard in the telephone: if the distance between B and A were greater, nothing was perceived in the telephone. However, if the circuit composed of B and the telephone were interrupted by a tuning-fork P, a sound was heard during somewhat one second and a half of the same pitch as the tone of the tuning-fork P, every time the primary current was sent through A, or broken. The intensity of this sound diminished as the distance of B from A increased, but was still perceptible wherever B was placed on the bar.

Thereupon the primary circuit to which belongs the primary coil A was interrupted by a tuning-fork Q. If no tuning-fork were in the circuit of B and the telephone, then only when B was near A a sound was heard of the pitch of Q; at a greater distance nothing was heard in the telephone. But if now a tuning-fork P interrupted the circuit of B and the telephone, a continuous sound was heard, even at much greater distances of B from A. When the pitch of P differed slightly from that of Q, beats were perceived, also when the frequency of P was nearly half that of Q. The interpretation of these facts is so apparent, that I need not dwell upon it. But these facts illustrate the principle on which Van Rysselberghe based his method of simultaneously sending telegraphic and telephonic signals along the same line.

I believe that the propagation of magnetic impulses along a bar of iron has to be studied in an entirely different way. We intend to make an attempt in this direction ere long.

Utrecht, July, 1892. V. A. JULIUS.

"The Limits of Animal Intelligence."

CLOSELY in connection with an observation I made the other day with respect to an argument of Prof. Pearson's, I should like to say a few words about a paper read by Prof. Lloyd Morgan before the International Congress of Experimental Psychology, on "The limits of animal intelligence." The first proposition he advanced, "That human psychology is the only key to animal psychology," and the deductions he subsequently drew, all implied that our knowledge of human psychology differed not only in degree, but in kind, from our knowledge of that of animals. Of course it is true that my knowledge of *my own* psychology does differ in kind from my knowledge of that of animals, but it differs in exactly the same way from my knowledge of that of all other men. If in no case is "an animal activity to be interpreted as the outcome of the exercise of a higher psychical faculty, if it can be fairly interpreted as the outcome of one which stands lower on the psychological scale," the same rule should be applied to the interpretation of human activities, for the only reason for distinguishing between human and animal psychology is that their activities do, as a matter of fact, differ. Human beings are of course distinguished from animals in other ways; in the structure of their limbs, for example; but there is no *a priori* ground for inferring from such differences any, and certainly not any particular, difference in psychological powers. And so far from its being permissible to infer such a difference from greater or less complexity of brain-structure, it is only because animals which when alive displayed great activities proved, on dissection, to have possessed complex brain structure, that we can infer any connection whatever between the two phenomena. As no man has ever dissected his own brain he cannot say that any particular structure is associated with those psychological powers of which alone he has any more direct knowledge. If, for example, I say "Morality involves a perception of the relation between the actual and ideal, and is based on introspection," I say this in consequence of my personal experience. I can only infer morality, introspection, and so on, in other beings, whether animals or men, by judging from their activities. And if "most cases of so-called morality in the dog can be otherwise interpreted," so also can most cases in other men. A fundamental distinction between the psychological powers of animals and men could only be established by showing a fundamental distinction between animal and human activities, as observed from outside by a third person. And though it is easy to show that there is a difference in degree, Prof. Morgan did not adduce any cases which even tended to show that there is any difference in kind. The cases he did adduce all tended the other way; and though this was doubtless because he only adduced difficult cases in order to show that his theory was capable of explaining them away, his explanations seemed to me, for the reasons I have given, insufficient.

Note.—The quotations are from a printed *précis* of his paper distributed by Prof. Lloyd Morgan at the meeting.

EDWARD T. DIXON.

12, Barkston Mansions, South Kensington, August 5.

Tropical Cyclones.

A FEW years ago I drew up some simple mathematical rules to aid the Jamaica Weather Service when in doubt as to the indications, and thinking that these rules may be of some use to other isolated or nearly isolated stations in the Tropics, I state them here, and give an example or two as to their application.

At the time and place of observation let

p = Reading of bar in inches and decimals of an inch, corrected for instrumental error, reduced to 32° F. and sea-level, and further corrected for diurnal variation.

p_m = Mean value of p for the time of the year.

$\Delta p = p_m - p$ = fall of pressure below the mean.

v = Velocity of the wind in miles per hour.

r = Distance of the centre of the cyclone in miles.

$\frac{dp}{dr}$ = Bar-gradient, or the fall of p per mile towards the centre at the place of observation.

$\frac{dp}{dt}$ = Rate of fall, or the fall of p per hour.

$\frac{dr}{dt}$ = Rate of approach of the centre in miles per hour.

Now let us suppose that the centre is moving towards the place; in this case we have

$$\frac{dr}{dt} = \frac{\frac{dp}{dt}}{\frac{dp}{dr}} = \frac{\text{Rate of fall}}{\text{Gradient}} \quad \ldots\ldots (1)$$

In Jamaica $\frac{dp}{dr}$ is found by an exchange of telegrams between Kingston and Kempshot, these places being on the line of usual approach, and 77 miles apart.

The next equation is based upon the results of observation:—

$$r = \frac{\Delta p}{2\frac{dp}{dr}} = \frac{\text{Fall below mean}}{\text{Twice the gradient}} \quad \ldots\ldots (2)$$

This equation must not be pressed; it is intended to be used when the centre is still a long way off.

Thus we have

$$\text{Time of arrival of the centre} = \frac{r}{\frac{dr}{dt}} = \frac{\text{Fall below mean}}{\text{Twice the rate of fall}} \quad \ldots\ldots (3)$$

This is an important equation, for it shows that the direct approach of a cyclone may be ascertained by the constancy in the computed time of arrival.

As an example, let us take the cyclone which passed over Kingston, Jamaica, August 18, 1880. This was before the Weather Service was established, and the indications of the advancing cyclone were confused by the existence of a small cyclone to the north-east of Kingston; there was no wind in Kingston until 8 p.m., and rain fell quietly in showers all that afternoon from a sky covered with stratus.

Kingston, Jamaica, August 18, 1880.

	p	Δp	$\frac{dp}{dt}$	Time of arrival.
7 a.m.	29·845			
9 ,,	·807	0·178	0·0170	2 p.m.
11 ,,	·777	·208	·0142	6 ,,
1 p.m.	·750	·235	·0120	11 ,,
3 ,,	·729	·256	·0225	9 ,,
5 ,,	·660	·325	·0595	8 ,,
7 ,,	29·491	0·494	0·1808	8.30 ,,
9 ,,	28·937			

From the last column it appears that from 7 a.m. to 1 p.m. the cyclone was not directly approaching, and from the logs of vessels and other information it is certain that the cyclone was passing south of Jamaica on a westerly course, and that between 1 and 3 p.m. it turned on its course and advanced directly towards Kingston. The centre arrived at about 9 15 p.m., lowest $p = 28·917$.[1] A warning notice was posted at 3 p.m., but had these rules been in existence, a better notice could have been posted at 5 p.m.

Now if the gradient be not known at an isolated station, it may sometimes be deduced from the theoretical equation—

$$\frac{dp}{dr} = 0·00007v \quad \ldots\ldots (4)$$

This equation is only to be used for considerable distances from the centre; and if v be small, or variable, or if it be mixed up with the sea-breeze, it cannot be used at all.

If $\frac{dp}{dr}$ be known, r is known from (2), and then some idea may be formed as to the magnitude of the coming disturbance. The following rule may prove useful:—

Let Δp_c be the fall below the mean at the calm centre of the cyclone; then, roughly—

$$\Delta p_c = \frac{\Delta p\sqrt{r}}{6}\left(1 + \tfrac{3}{4}\Delta p\sqrt{r}\right) \quad \ldots\ldots (5)$$

Now $\frac{dp}{dr}$ is unknown in the example above; but if we take $\frac{dr}{dt} = 18$ from the subsequently known circumstances, (1) gives $\frac{dp}{dr} = 0·0012$ at 3 p.m.; (2) gives $r = 106$ at the same hour which happens to be right; and (5) gives $\Delta p_c = 1·3$, which is a little too large, the observed fall at the centre being about 1·1.

As another example, let us take the great hurricane in Mauritius on April 29 this year. Some valuable notes by Dr. Meldrum are published in NATURE, June 9, but unfortunately the readings of the barometer are not corrected for diurnal variation, although the given values of $\frac{dp}{dt}$ are so corrected; and I can only apply approximate corrections, and so obtain approximate values of Δp.

---

[1] See "Jamaica Meteor. Obs.," vol. i. (Introduction).

Mauritius, *April* 29, 1892.

	p	Δp	$\frac{dp}{dt}$	Time of arrival.
6 a.m.	29·668	0·282	0·018	2 p.m.
8 ,,	·597	·353	·029	2 ,,
9 ,,	·536	·414	·063	1 ,,
10 ,,	·440	·510	·094	1 ,,
11 ,,	29·304	0·646	0·131	1.30 ,,

The computed time of arrival is therefore 1.30 p.m., and the agreement in the last column shows that the centre was directly approaching the place of observation, and it really arrived there at 2, or 2.30 p.m.

Now at 6 a.m. the wind was 22·4 miles an hour: (4) gives $\frac{dp}{dt} = 0·0016$; (2) gives $r = 104$; and (5) gives $\Delta p_c = 1·5$, which is a little too small, the observed fall at the centre being about 2·0. If, however, we compute Δp_c for 9 a.m., we get 2·4, which is a little too large; and as in the case of time of arrival, we should be guided by a series when possible.

Jamaica, July 29. MAXWELL HALL.

A Sparrow's Antipathy to Purple.

I HAVE but just seen your number for March 10. About five years ago I knew a tame sparrow with a great antipathy for purple. It was brought up in a room, but not, or seldom, caged. It lived four or five months. A piece of blue paper placed over its food would cause it to hesitate, though if hungry it would eventually draw the paper aside; a person coming into the room wearing a blue dress would make it quite wild, and a habit of mischievously pecking at a certain part of the wall of the room was successfully stopped by hanging a piece of blue paper there. This sparrow was taught to be cleanly in its habits. I had put off writing this to you in hopes that others who saw more of the sparrow would have written a more detailed account, but trust this letter may not be too late for any one interested to get a young sparrow from the nest this year and rear it. Sparrows have not yet reached Borneo. G. D. HAVILAND.

Sarawak, June 17.

Bumping in the Lane Fox Mercurial Pump.

CAN any reader of NATURE favour me with a method by which the bumping in the Lane Fox pump may be obviated? I find that when exhaustion is pressed to a certain point, the bumping becomes so violent, in spite of the utmost care in lowering the reservoir, that the bulb of the pump is constantly cracked. D. G.

Lahore, July 25.

CARL SCHORLEMMER, LL.D., F.R.S.

CARL SCHORLEMMER having been my friend and colleague in Owens College for more than thirty years, it is with a sad pleasure that I take up my pen to record in the columns of NATURE some few details of his character and work. He had not, like his predecessor Dittmar, been a fellow student with me in Heidelberg, but had worked at chemistry in Darmstadt, where he was born, and at Giessen. In 1858 Dittmar, who up to that year had been my private assistant, obtained the College appointment of Demonstrator, and he strongly urged me to offer his vacant post to his friend Schorlemmer, a young man of great promise. From the time of his arrival in Manchester until the day of his death I do not recollect that in all the intercourse of those years Schorlemmer and I ever had a single serious difference. Whilst my private assistant he and I examined the relation which the aqueous acids exhibit as regards boiling point and composition, and I remember well the difficulties we had to contend with in distilling fuming nitric and hydrofluoric acids under pressure, and I also remember how successfully he met them. Once, I know, he got some fuming hydrofluoric acid on his hand, and he bore the scar of the serious burn to the end. This work with me was his apprenticeship. In a short time Dittmar left us, and Schorlemmer took his place as the official Laboratory Assistant, and as we had not many students at that time, he had leisure to begin the hydrocarbon work which has placed his name high in the list of organic chemists of the century. In 1861 the late Mr. John Barrow, of the Dalton Chemical Works, Gorton, brought me a sample of the light oils which he had obtained in the distillation of cannel coal. At that time our knowledge of the chemical composition of the low-boiling coal-oils was very incomplete, and I urged Schorlemmer to undertake the investigation. This was the beginning of the work which led to a result which altogether modified the existing ideas concerning the constitution of the paraffin hydrocarbons, and paved the way for the sound foundation upon which the organic portion of our science has since been successfully laid. In order to appreciate Schorlemmer's results let us for a few moments glance at the position of the question when he commenced work. Before 1848 the only known member of the paraffin series of hydrocarbons, was methane CH_4. In the above year the researches of Kolbe on the electrolysis of the fatty acids, and of Frankland on the isolation of the alcohol-radicals, opened out new fields yielding a rich harvest. Each molecule of these latter hydrocarbons was supposed to contain two molecules of the radical methyl being represented as $\left.\begin{matrix}CH_3\\CH_3\end{matrix}\right\}$, whilst together with these a second series of hydrides was believed to exist, $\left.\begin{matrix}C_2H_5\\H\end{matrix}\right\}$ ethyl hydride standing in the same relation to the radical as an alcohol does to an ether. The truth of this view seemed confirmed by Wurtz's discovery of the existence of the so-called mixed radicals in which two molecules of different hydrocarbons, such as ethyl and amyl $\left.\begin{matrix}C_2H_5\\C_5H_{11}\end{matrix}\right\}$ occurred. How was this question to be settled? Schorlemmer at once seized upon the correct method of solution and carried it out successfully. If, said he, the radical methyl $\left.\begin{matrix}CH_3\\CH_3\end{matrix}\right\}$ is identical with hydride of ethyl $\left.\begin{matrix}C_2H_5\\H\end{matrix}\right\}$ not only must these two bodies possess the same properties, but both bodies must yield the same product, viz., ethyl chloride, on treatment with chlorine. This identity he proved, not only in the above—the most simple case—but in the more complicated cases of ethyl-amyl $\left.\begin{matrix}C_2H_5\\C_5H_{11}\end{matrix}\right\}$ and of di-amyl $\left.\begin{matrix}C_5H_{11}\\C_5H_{11}\end{matrix}\right\}$ as these hydrocarbons yielded respectively chloride of heptyl and chloride of decatyl, $C_7H_{12}Cl$. and $C_{10}H_{21}Cl$. It is difficult to overrate the importance of this apparently simple discovery. It laid for ever the ghost of the existence of two sets of isomeric hydrocarbons of the paraffin series, and paved the way for Kekulé's theory of carbon combination, upon which the whole modern theory of organic chemistry is based. So to Schorlemmer belongs the credit of placing in position the foundation-stone of our science. And at once his name became known as a master wherever chemistry is studied; so that in 1871 the Council of the Royal Society admitted him to the Fellowship at once, an honour conferred nowadays on few.

But it was not only as an expert experimentalist that Schorlemmer excelled, and his thirty-two papers catalogued in the Royal Society list prove that he was a successful one. He possessed an exhaustive knowledge, uncommon amongst chemists, of the literature of his special science in all its varied departments. If any of our men wanted a quick reference to either recent or ancient work, it was always "Go and ask Schorlemmer," and they seldom came empty away. But his acquaintance with other sciences was also considerable. If he had not been a distinguished chemist he would have made an equally distinguished botanist. He likewise possessed in full measure that dogged power of work which distinguishes the German. I was especially fortunate in securing his co-operation as co-author of the Treatise. The success of my little book—as to which no one was more surprised than myself—induced me to set about the task of writing a larger and more complete work. I soon found that the other very various and pressing duties of my position rendered it impossible for me to do all the work myself, and my friend Schorlemmer joined me in this somewhat laborious business. To him the organic part almost entirely owes its being, whilst in the inorganic portion his assistance and suggestions were most valuable. We published the book simultaneously in Germany and England, and it is not too much to say that in both countries the work has become a standard one. For the last few years of his life this was his main work. Only those few men who have lately attempted the task of writing even a moderately complete treatise on modern organic chemistry can know what serious labour such work entails. Several distinguished chemists have given up the task as hopeless, and have not completed what they had begun. If Schorlemmer's life had been spared he would have brought his work to a conclusion, cost what it might. Our consolation—and it is but a poor one—at his early death (for he was only fifty-eight), must be that, so far as the chemistry of the hydrocarbons and their derivatives are concerned, his manuscript is complete, and in the hands of Messrs. Vieweg. A mass of material he has gathered together for the remaining organic compounds in which nitrogen occurs as a constituent element. It will be my task to see whether this last portion of the work is complete, and if not, how it can best be brought up to the level of the day.

As a historian of our science, I think that the designation of him by his German friends as the "English Kopp" is a just one. Only a few weeks before his death he talked to me with pleasure of the results of his work on an introduction to the history of chemistry, which had engaged his attention for many months past. Fortunately, he had the rare power of writing so that his manuscript was at once ready for press. Hence, although a fragment, his history so far as it goes—and I believe it goes as far as the end of the eighteenth century—is complete. We shall all look with interest to its speedy publication, and from what I know of the author's works and ways, I shall be disappointed if this fragment does not throw a new light on many dark pages in the early history of our science. One word more as to his character. I have said that we never had a difference, and I believe from what I know of his other friends that they would say the same. He was of a retiring, most modest, and unassuming disposition. To only a few of his intimates, German and English, were his true colours visible. As a laboratory teacher he was excelled by few, merely as a lecturer by many. But although, like some other eminent lecturers, his diction may have been faulty, the staple article was there, and I never met a real student amongst all those who passed through his hands who did not express his admiration for the man, and his sense of the obligation which he felt for the masterly instruction which the Professor always and most readily gave, whilst the long list of honours which his men gained in organic chemistry, both at London and afterwards at Victoria, proved that his teaching was not in vain. True to his science, he valued chiefly the respect and affection of his colleagues and pupils. In society he did not shine, nor did he take any leading part in the government of the College or in the foundation of the University, although those of us who were more active in these matters could always count upon his support in all questions in which the interests of science were concerned, and if he usually preferred to be at his own desk rather than to spend his time listening to the often tedious discussions of the Senate meetings, he was always at hand when a vote was needed to carry out some measure of scientific reform. Although for many years a naturalized Englishman, and enjoying and appreciating English freedom and English ways, he retained more than is usual, a lively interest in the welfare of the "Vaterland." I knew but little of his political views, for these he did not obtrude on his friends, though he held decided ones. He believed in popular freedom and popular rights, and was a strong supporter of the German Social Democratic party, many of the leaders of this movement, both in Germany and in England, being his intimate personal friends. But with these matters we here have little to do. We here have to recognize the scientific work which he has done amongst us, to record our appreciation of that work, and to express the regret of all interested in science at his untimely death.

H. E. Roscoe.

SCIENTIFIC INVESTIGATIONS OF THE SCOTTISH FISHERY BOARD.

The Fishery Board for Scotland has issued its Tenth Annual Report (for the year 1891). It is divided into two parts—the general report, and the report on salmon fisheries. We reprint from the general report the passage relating to the scientific investigations carried on since the Board was reconstituted ten years ago:—

The following is a statement of the sums which have been sanctioned during each of the following years and spent by the Board on scientific investigations:—

Year.	Sanctioned.	Spent.
1883–84	£300	£300 13 7
1884–85	1600	1430 0 11
1885–86	1500	1500 0 0
1886–87	2000	1647 5 3
1887–88	2000	1843 4 5
1888–89	2000	1804 4 3
1889–90	2000	2026 10 0½
1890–91	1800	1792 13 4
	(With £200 for travelling expenses.)	
1891–92	£1800	Do.

In addition a sum of £2500 was applied in 1886–87 for the purchase of the steamer *Garland*, and £500 per annum allowed for its maintenance, which was increased first to £900, and afterwards to £1200 a year.

When the Board commenced its operations, it was a new departure in State administration. The Fisheries Commission of the United States was only established in 1871, and we were without the experience which has since been gained in America, Germany, Norway, and other countries bordering on the North Sea. The directions of the Act of Parliament creating the Board were very general. We were appointed to "take cognisance of everything relating to the coast and deep sea fisheries of Scotland, and take such measures for their improvement as the funds under their administration not otherwise appropriated might admit of, but without interfering with any existing authority or private right." Hitherto the fisheries had been practically left to take care of themselves. During the administration of the old Board, which had existed from 1809 under the name of the Commissioners of the British White Herring Fishery, scientific investigations had indeed been made from time to time into special points, such as the spawning of the herring, the capture of immature herrings by sprat fishermen, and the action of the beam-trawl on herring spawning-beds. These inquiries were, however, limited both in character and extent, and were merely incidental to certain questions prominent for the time being. The absence of definite scientific knowledge relating to the fisheries had been felt and commented upon by Royal Commissions appointed to enquire into fishing questions; and when the new Board came into existence in 1882, it was found that, without further information as to the habits and life-history of the food-fishes, it would be impossible to submit satisfactory reports to Parliament either as to the improvement or the regulation of the fisheries. It was accordingly resolved that scientific investigations should be instituted under a committee, consisting of Prof. Ewart (Convener), Sir James Maitland, Sheriff Forbes Irvine, and Mr. Maxtone Graham. This committee acted until 1886, when it was dissolved; and, in 1887, another committee was formed, consisting of Prof. Ewart (Convener), Sir James Maitland, Mr. William Boyd, and Mr. W. Anderson Smith, which continued till 1889. Since the dissolution of this committee the scientific work has been under the immediate control of the Board, with Dr. T. Wemyss Fulton as scientific secretary, but all the members feel, and desire specially to acknowledge, the valuable assistance which has been rendered by Sir James Maitland and Mr. Anderson Smith.

Before describing the investigations undertaken, a word must be said as to the means which have been at the disposal of the Board. In 1884 a marine laboratory was established at St. Andrews, with the co-operation of Prof. McIntosh, F.R.S., who was at the time engaged in making scientific investigations for the Royal Commission on Beam-Trawling, under the late Lord Dalhousie; and this laboratory has continued in active operation ever since under Prof. McIntosh's charge. In 1885 another laboratory was erected at Tarbert, Lochfyne, which was placed under the charge of Mr. George Brook, F.L.S., and was occupied until 1887. During 1886–87 a portion of Rothesay Aquarium was made use of, and from 1884 until 1889 part of the scientific work was carried on at the Natural History Department of the University of Edinburgh, under the charge of Prof. Ewart. Subsequently a marine laboratory was built at Dunbar, which has since been added to, and in connection with which the Board are now erecting a large hatchery for the propagation of sea-fish. In addition to the laboratories mentioned, the fishery cruisers have occasionally been engaged in aiding the scientific inquiries, as have also the staff of Fishery Officers around the coast. Since 1886 the small steam-vessel *Garland*, although not at all sufficient for the work, has also rendered important services.

At the time when the scientific investigations were begun very little was known regarding the habits of sea-fishes. Fishermen, who presumably ought to know something of the life-history of the fishes they catch, knew, as Prof. Huxley has remarked, very little beyond the best way to catch them. Yet from the earliest period until comparatively lately, the practice has been to shape fishery legislation in accordance with local desires or the popular opinion prevailing at the time, and not upon ascertained conditions. A study of the statutes dealing with sea fisheries, especially those passed by Parliament from the middle of last century to about the middle of this, shows that vast sums of money have been expended uselessly, and injurious restrictions imposed for reasons which scientific investigations have now proved were illusory. About thirty years ago, however, an important change in this system was effected. Van Beneden on the continent, and Prof. Huxley, Mr. Spencer Walpole, Mr. Shaw Lefevre, and others in this country made a stand against haphazard regulations, and in Great Britain their action found practical expression in the liberating Act of 1868 (31 and 32 Vict. c. 45), which repealed or amended sixty-four fishery statutes, and restored liberty of fishing. The Royal Commissioners who brought about this reform (the late Sir James Caird, Prof. Huxley, and Mr. Shaw Lefevre) refer in their report to the absence of knowledge about the habits of sea fishes, their reproduction, spawning-places, and conditions of existence which is essential to effective regulation of the fisheries.

An indication of the lack of accurate knowledge on these subjects as lately as 1883 was afforded at the London International Fishery Exhibition in 1883, when a high authority thus described the condition of things at that time: "It is a very striking fact that the one point on which all speakers at the conferences held during the past summer at the Exhibition were agreed was this—that our knowledge of the habits, time and place of spawning, food, peculiarities of the young, migrations, &c., of the fish which form the basis of British fisheries, is lamentably deficient, and that without further knowledge any legislation or attempts to improve our fisheries by better modes of fishing, or by protection or culture, must be dangerous, and indeed unreasonable."

It is a source of satisfaction to the Board that their labours in this field of fishery work, even for the comparatively short time over which they have extended, have yielded successful results, and have contributed materially to the advancement of that knowledge of fishery problems, the want of which was felt and deplored by the Royal Commissioners of 1866. The scientific work carried on by the Board, the chief results of which have been described from year to year in their annual report to Parliament, may be summarized briefly as follows:—

(1) Inquiries into the influence of beam-trawling on the fish supply, especially within the territorial waters; the capture and destruction of immature fish by various modes of fishing; the condition of the inshore fisheries for shell-fish and the supplies of mussels and other bait for line fishermen; surveys and examination of the fishing grounds, &c.

(2) Investigations into the food, fecundity, reproduction, habits and migrations of the food fishes, the location of their spawning-grounds, and of the nurseries of young fish, the time and duration of spawning, &c.

(3) The study of pelagic and demersal ova, and of the development of the food-fishes and edible molluscs from the egg onwards.

(4) Inquiries into the micro-organisms in river waters, and associated with salmon disease, and into the food of fishes in inland waters.

(5) Observations on the temperature, salinity, and physical conditions of the sea around the coast.

(6) The artificial propagation of sea-fish and shell-fish to re-stock depleted grounds.

The investigations into the influence of beam trawling, which have been carried on with great regularity and care, have furnished a mass of scientific and statistical evidence unexampled in the history of any fishery, and have been followed by the prohibition of this mode of fishing within the territorial seas. As stated in former reports, various portions of the inshore grounds were for experimental purposes closed against beam-trawling, and by the Herring Fishery (Scotland) Act of 1889, the territorial waters were included in the prohibition, certain powers being reserved to the Fishery Board. Closely related to beam-trawling is the capture and destruction of immature fish, which is generally regarded as the most important of the fishery problems awaiting solution in the immediate future. In certain foreign States and English fishery districts the landing or sale of immature fish under certain sizes has already been made penal; and in 1890 an International Fishery Conference was specially convened in London to consider this subject so far as it affected the diminution of the fish supply from the North Sea. Extensive observations have been made by the Board as to the distribution of immature fish on the east coast of Scotland at various distances from shore and in water of different depths; the minimum size at maturity of the different species and the proportions captured by various modes of fishing, with especial reference to the mesh of trawl-nets, have been ascertained, as has also the action of the beam-trawl in destroying immature fish according to the time the net is down and the nature of the bottom. The results were embodied in a report which was prepared by Dr. Fulton, under directions of the Board, and was described (we believe with perfect accuracy) by the vice-president at the Conference "as one of the most important, if not the most important, document that had up to the present been contributed to the Fishery literature of this country."

The inquiries into the food and propagation of the edible fishes have been also prosecuted on an extensive scale. The food-material of nearly 20,000 specimens caught at various parts of the coast and at all seasons of the year has been examined, and this research has yielded valuable results both in regard to the protection and regulation of the fisheries and the increase of the fish supply by artificial means. The fecundity of nearly all the food-fishes has been determined, the nature of pelagic and demersal ova has been carefully studied, and the distribution of the former in the waters over the breeding grounds and along the coasts investigated. The development from the egg onwards, and the characteristics of the young of the majority of the edible fishes have been described—including the herring, haddock, whiting, cod, ling, turbot, plaice, lemon sole, flounder, &c., and also of the most valuable forms of bait, the mussel and the clam. The spawning of the herring and of the other food-fishes has received special attention. Since 1888 upwards of 30,000 white fish—such as cod, turbot, plaice, &c.—have been individually examined. By this means the time and duration of the breeding season has been determined, and the important fact has been proved that on the east coast of Scotland, where the investigation was mainly carried on, the spawning-grounds of the valuable food-fishes (cod, haddock, plaice, turbot, &c.) generally lie outside the territorial limit—contrary to the belief formerly held—and that only forms of comparatively little value, such as the flounder, dabs, and gurnards, &c., spawn within the three-mile limit. The importance of these facts cannot be over-estimated. They bear directly both on the question of establishing a close-time and the measures proper to be taken for the regulation of fishing on the breeding-grounds. The trawlers, driven outside the inshore waters, generally take to the breeding-grounds, for there the hauls are most abundant. The significance of this fact, in connection with the falling off in the inshore fisheries, is becoming too grave to be longer overlooked. The growth of population has been followed by an increase in the demand for fresh fish, the extension of the means of distribution has ministered to this demand, and if the floor of the ocean is to be swept without public regulation, the ordinary fishing-grounds will prove inadequate to maintain the supply. The destruction of spawning fish is proving a serious evil. In Germany, where this matter has been carefully examined, it is now held to be more important to protect the spawning-banks, than to prevent the destruction of immature fish. Some of our fisheries are, in fact, in danger of being exhausted unless judicious regulations are rigidly enforced.

During the last three years experiments have been carried on to determine the migratory movements of fish, and nearly 3000 have been labelled and returned to the sea. A percentage of these has been recovered, and steps are now being taken to apply the same method on a large scale to the herring. The experiments are not sufficiently advanced to justify any final conclusion as regards all fish, but undoubtedly as regards many of them the facts already ascertained prove that until they reach a certain size they do not leave the territorial waters.

The means of increasing the diminishing fisheries for shell-fish have received careful attention. Surveys have been made of the more important mussel-beds on the east coast, the extensive clam-bed in the Firth of Forth, the cockle beds at Barra, and a detailed examination of the great mussel-growing area in the Clyde is at present in progress. The French system of growing mussels on wattled bouchots has been tested side by side with the bed-system, and a series of experiments have been made on board the *Garland* to test the comparative efficiency of different natural baits, and of various artificial substitutes. A physical and biological investigation has also been made of a number of sea-lochs on the west coast, in order to ascertain their suitability for the growth and culture of oysters (the Scottish oyster having sunk to a very low point), and a special lobster pond has been constructed at Brodick, Arran, in which about 200,000 young lobsters were hatched last year.

The physical observations into the temperature and salinity of the sea have been carried on on board the *Garland* and the fishery cruisers, and at ten fixed stations daily—five on the east coast and five on the west. By the courtesy of the Northern Lighthouse Board, observations are allowed to be taken daily at the Bell Rock and Oxcar Lighthouses, the lightship at the North Carr, and also at the mouth of the Tay. Many thousands of observations are thus made every year, and several valuable reports have already been published.

From this brief summary of part of the work done, it will be seen that considerable progress has been made since 1883 in extending the knowledge of the habits and life-history of the food-fishes; and it is gratifying to learn that the results obtained by the Board have been gratefully acknowledged by high authorities, and found useful in other countries.

In recent years the attention of the authorities of various maritime States, especially those around the North Sea, but also in the Mediterranean and in America, has been forcibly called to the diminution of the fish-supply within the territorial seas and on much-frequented fishing banks off shore. The falling off in the supply of valuable flat fishes, such as turbot, sole, and plaice, from the North Sea, has led to various conferences of those engaged in the fishing industry. At the International Fishery Conference held in London in 1890, at which representatives were present from Germany, Denmark, Holland, France, Belgium and Spain, it was resolved that scientific investigations should be carried on by each country, particularly into the capture and destruction of immature fish by the beam-trawl, prior to the assembling of an official International Conference to deal with the subject by international agreement; and at a conference of representatives of the fishing industry held in London last February resolutions were passed, that in view of the diminution of the valuable food-fishes, the hatching of sea-fish should be undertaken on a large scale, and measures adopted to prohibit the sale of immature flat fishes under a certain size. The decrease in the fish supply from the off-shore banks has not yet become so marked off the Scottish coast as is the case further south; but from the statistics given below as to the yearly increasing number of Scottish beam-trawlers; the flocking northwards of English vessels from their own depleted grounds; and the actual diminution in the quantity of flat fish landed there is reason to apprehend that in the course of very few years a similar result will be brought about here. As has been stated above, the Board are at present having erected at Dunbar, by means of the ordinary vote for scientific investigation, on a site granted by the War Office and the Council of the Burgh, a large hatchery for sea-fish, with the necessary tanks and pumping apparatus, which, when complete, will permit of several hundreds of millions of the food-fishes being hatched every season and planted on the fishing-grounds. It will therefore be possible for the first time in this country to adopt active measures to directly add to the fish supply, as has already been done in the United States, Norway, Canada, and Newfoundland.

NOTES.

AMONG the honours announced at the change of Ministry the Privy Councillorship conferred upon Prof. Huxley not only establishes a precedent, but affords an indication that the neglect of the claims of men of science, whether they be servants of the Crown or not, to the ordinary national distinctions is not likely to be so marked in the future as it has been in the past. Six years ago or thereabouts, Prof. Huxley was allowed to leave the public service without the slightest recognition of the value of the work he had done in many capacities during some forty years. No better way of making the so-called "honours" ridiculous can be found than in generally omitting to confer them upon persons of distinction—persons known to the nation as devoting their lives to the national welfare in some walk or other.

WE have learned with regret a rumour to the effect that th Admiralty has declined to render the assistance in carrying observers and instruments for which the Royal Society made application some time ago to further the observations of the total solar eclipse in Senegambia next April. If this be confirmed, the expedition will in all probability be abandoned. Such a state of things requires no comment of ours.

A MEETING of the Swiss Society of Natural History is announced to take place at Basle, from September 4 to 7, under the Presidency of Prof. Hagenbach-Bischoff, and the following communications have been aranged for:—"The Origin of Swiss Lakes," Prof. A. Heim, Zurich; "The Thermal Conditions of the Lake of Geneva," Prof. F. A. Forel, Morges; "The Biological Conditions of the East-African Steppe," Prof. C. Keller, Zurich; "The Metamorphosis of Alpine Rocks," Prof. C. Schmidt, Basle; "The Evolution of Human and Animal Physiognomy," Prof. W. His, Leipzig; "Studies on the Veddahs, the Aboriginals of Ceylon," Dr. Fr. Sarasin, Berlin. A special invitation is given to foreign students to join the meeting.

ACCORDING to the *Times* a telegram has been received from Tromsö announcing that the *Manche* which left Leith on July 20, for Jan Mayen Island, in the Greenland Sea, reached its destination on the 27th. The island had not been visited for ten years. The vessel went round it and then proceeded to Spitzbergen, where it made important collections of reindeer, foxes, birds, and fossils in Ja Fiord and Bel Sound.

MR. RISELY GRIFFITHS, the Administrator of the Seychelles, visited the Island of Aldabra in May last. In a report to the Colonial Office communicated to Kew, he gives the following particulars respecting the gigantic land tortoises :—"The following morning I went on shore to visit Mr. Spurs' establishment, and observe some of the natural peculiarities of this extraordinarily-formed island, which, except here and there, appears to be one mass of very ancient coral, which has been washed for so many centuries by the sea that all the softer portions have been washed out, and the remainder is hard and ragged, and therefore is difficult to walk over. Curious to state, small trees, shrubs and vines flourish over it, and in these inextricable places, which are of vast extent, do the enormous land tortoises find a genial and apparently prolific existence. When Mr. Spurs first went to Aldabra he was of opinion there were very few of them left ; but he now states that there cannot be less than one thousand in all the island. I made him repeat this statement more than once, as I was sceptical about so large a number ; but he assured me that a few hundreds would not accurately describe their number."

THE Tuesday evening lectures at the Royal Victoria Hall, Waterloo Bridge Road, will be resumed in September, and on the evenings of September 6, 13, and 20, respectively, Prof. B. J. Malden will lecture on "The Wonders of the World," "A Holiday in Sweden and Denmark," and "Australia."

ACCORDING to the *North British Agriculturalist* the plague of voles from which farmers in the Border districts have for some time past suffered much inconvenience and loss, is, notwithstanding the strenuous efforts put forward for the abatement of the plague, on the increase. The grass lands are so thickly set with the nests of the voles that much difficulty is experienced in cutting them, and the vermin are now making their abode in the corn-fields, which are in consequence also being destroyed.

CÁNOVAS AND TRAYNOR, 3 Calle de Santa Catalina, Madrid invite subscriptions to a facsimile reproduction of the first geographical chart of America (1500), by Juan de la Cosa, Columbus's sailing-master in his first and second voyages. It will be printed in the original colours, from which black, by the way, is absent. The work will be published in three forms, one—the popular—at 12s., another in vellum at 20s., and the third in parchment at £20. The parchment edition will be hand coloured.

PROF. FLÜCKIGER has sent to the President of the Pharmaceutical Society, as representing the British subscribers to the Flückiger testimonial, a bronze replica of the medal which was presented to him, and expresses the hope that it will be accepted as a sign of his gratitude and a slight proof of his appreciation of the friendship and encouragement he has always met with in England.

WE extract from the *Bollettino Mensile*, of the Meteorological Observatory of Riposto, the following details respecting the recent eruptions of Mount Etna. The crater had shown extraordinary activity from the beginning of July, and on the night of the 8th–9th, a severe shock in all the surrounding region announced the probability of an approaching eruption. At 1.20 p.m. on the 9th the south slope of the mountain burst open, at about 5000 feet above the sea, forming at once several mouths emitting lava, stones, and incandescent masses, as well as enormous quantities of sand and black smoke. At times large blocks were hurled to a height of about 1300 feet. Several of the mouths united, and formed three craters in an almost direct line from north to south, from two of which the lava encircled Monte Nero like an enormous river, while the third emitted masses of stones and cinders. The eruption continued with more or less intensity all the month, but showed signs of diminishing on the 31st. The lava devastated much fertile country, but fortunately its course was checked by the deposits of former eruptions ; if this had not been the case several of the villages would have been in great danger. This eruption was noteworthy for the enormous quantities of smoke and sand emitted, and for the scarcity of seismic motions ; the lava resembled physically that emitted in the eruptions of 1883 and 1886.

THE thirty-ninth Report of the Department of Science and Art of the Committee of Council on Education is now ready, as is also the Directory (revised to June 1892), with regulations for establishing and conducting science and art schools and classes.

MESSRS. GIBBONS, of Liverpool, have issued a small handbook respecting the Department of Engineering in connection with University College, Liverpool, which should prove of much service to intending students, who will find in it all the information they are likely to require with reference to fees, subjects, evening lectures and classes, scholarships, certificates, &c., &c.

THE twenty-fifth annual report of the Peabody Institute of the City of Baltimore has been issued, and seems in every respect highly satisfactory. Incandescent electric lamps and appliances have been placed in the large hall and reading-room during the year, accessions to the library have been numerous and valuable, and the lectures were attended by larger audiences than in the preceding year. Another encouraging item in the report is that there was an increase in the number of applications for books relating to science, amongst the subjects which appear to have grown in favour being anatomy, astronomy, chemistry, mathematics, medicine, and natural history.

THE annual announcement of Courses of Instruction in the Colleges at Berkeley, Cal., for the academic year 1892–93 has recently been issued.

THE Calendar of University College, Bristol, for the Session 1892—93, has just been issued.

THE second edition of Mr. W. F. Kirby's "Elementary Text-Book of Entomology" has been published within the last few days by Messrs. Swan Sonnenschein and Co. The author has not thought it necessary to make any extensive alterations in the text or plates, but the following additions have been made to the work :—An appendix, giving further particulars respecting many of the insects mentioned or figured, and a complete index.

IN the *Board of Trade Journal* for August are to be found articles on "Chemical Industry in Germany," the "Sicilian Sulphur Industry," and "Cinchona and Indigo Cultivation in India."

THE current number of the *Journal of the Society of Arts* is, in the main, devoted to the publication of Prof. George Forbes' first lecture on "Developments of Electrical Distribution."

THE June number of the *Agricultural Gazette of New South Wales* contains the continuation of two articles by Mr. P. Turner, on "The Grasses of Australia," and "New Commercial Crops for New South Wales," "Notes on Economic Plants," "The Sugar Cane Disease on the Richmond and Clarence Rivers," and many other items of interest.

THE *Korean Repository* for June, which has just come to hand, has an interesting article by Rev. D. L. Gifford on "Ancestral Worship as practised in Korea."

MESSRS. CROSBY LOCKWOOD AND SON announce for early publication a new work by Mr. J. E. Gore, entitled "The Visible Universe, Chapters on the Origin and Construction of the Heavens."

British Rainfall for 1891, compiled by Mr. G. J. Symons and Mr. H. T. Wallis, has been published, and in consequence of the exceptional character of the year of which it treats, is rather later in making its appearance than its predecessors have been. The Devonshire blizzard was the cause of much work, and praise is due to those observers who were brave and persevering enough to take their observations, notwithstanding the very exceptional difficulties by which they were confronted. One observer was barricaded with five feet of snow against every door, and another—a lady—finding that the wind had swept the grass clean all round the rain gauge and piled the snow more than five feet deep near the entrance gates to her house, wrote to enquire what she was to enter as the depth of the snow.

Symons's Monthly Meteorological Magazine for August contains a summary of the climate of the British Empire for the year 1891, compiled from sixteen representative stations. The highest shade temperature occurred at Melbourne, 103° in January. This is the first occasion since the publication of these interesting tables in 1884, that the temperature of Melbourne has exceeded both Adelaide and Calcutta. In connection with high temperature, attention is drawn to the record at Alice Springs in the centre of Australia, which shows an absolute shade maximum of 117° in December, and an average maximum of above 100° for the month. The extreme maximum in the sun 165°, and the lowest mean humidity 57 per cent, were recorded at Adelaide. Winnipeg, as usual, had the lowest shade temperature, – 34° ·5, in February, as well as the greatest total range 128° ·1, and greatest mean daily range 22° ·9. Ceylon recorded the highest mean temperature, 80° ·7, and also the least range in the year, there being only 24° ·3 between the maximum of the hottest day and the minimum of the coldest night. Malta usually has the smallest rainfall or the least cloud; this year, however, Adelaide had the least rainfall, 14 inches, and Bombay the least cloud, the average amount being 3·5. The greatest rainfall was at Colombo, Ceylon, 119 inches. It is unfortunate that both the West Indian returns have had to be omitted owing to incompleteness.

ABOUT the middle of last week the low pressure areas which advanced over this country from the south-westward caused a rapid rise of temperature in England, the maximum shade temperatures reaching 83° in the south and east. These conditions were accompanied by violent thunderstorms over the southern, midland, and eastern counties on Thursday and Friday, the area embraced by the storm extending from Devonshire in the west to Norfolk in the north-east, while the rainfall was very heavy, amounting to 1·4 inch in several parts. During the early part of the present week the temperature continued high over the greater part of England, being about 10° above the mean for the time of year, but was much lower in Scotland and Ireland. Conditions were again unsettled on the 23rd, and about 1·5 inch of rain was measured in the south-west of Ireland on that morning, while areas of low pressure lay over our south-west coasts, and severe thunderstorms occurred in the evening over all the southern half of England. The heat on the Continent has been excessive, the thermometer in the shade registering 100° and upwards at many stations, and even reaching 108° at Biarritz and Bilbao. During the last few days, however, the weather has become somewhat cooler over Europe, although very high temperatures were still maintained. During the week ended the 20th inst. the rainfall exceeded the mean in Ireland and Scotland, but in most of the English districts there was a considerable deficit (except in the south and east, where there was an excess, owing to the thunderstorms). There still exists a deficiency in all districts from the beginning of the year amounting to 5 inches in the south and to 8·6 inches in the south-west of England.

THE firm of P. J. Kipp and Sons, Delft, have constructed a new form of their electrodynamometer for the measurement of telephonic currents, in which several improvements have been introduced. As in the old form, in accordance with the suggestion of M. Bellati (Atti del R.I. Ven. 1883), a cylinder of soft iron wires takes the place of the usual movable bobbin. The cylinder becomes magnetized under the action of the current in the fixed coil; its magnetization being proportional to the strength of the current when sufficiently weak, and becoming reversed on the reversal of the current. The instrument is therefore eminently suitable for the measurement of weak alternating currents. The coil is wound in two parts, which may be used in series or in multiple arc, the resistance of each being about 250 ohms. A damping arrangement, similar to that employed in Thomson's quadrant electrometer, can be used. When the vibrations are not damped, speaking in a low voice into a Siemens telephone in connection with this instrument produces a deflection of 180mm. on a scale placed at the proper distance from a mirror which is attached to the iron cylinder. If one speaks at the distance of three or four metres from a microphone placed in the primary circuit of a small induction coil—the electrodynamometer being in the secondary circuit—a deflection of 48mm. is obtained. The price of the instrument is 225 or 240 francs, according as a concave, or a plane, mirror is supplied. A guard ring of soft iron can be supplied for twenty-two francs additional. The firm believe that the instrument will be of great use to physiologists. It is largely used in continental laboratories.

REPORTING lately to the Société d'Encouragement on the industrial preparation of carbonic acid in France, commenced by M. Gall, M. Troost points out that in Germany, which preceded France in this matter, what greatly stimulated the work was the consumption of beer, as it was found that by pressure of carbonic acid on beer, the latter could be brought up from cellars to bars in excellent condition, while compressed air spoiled the beer. In France, on the other hand, success has been due to the large quantities of salicylic acid used in medical treatment, this substance being largely produced by the reaction of liquid carbonic acid on sodium-phenol. The *Compagnie générale des produits antiseptiques* has works near Hermes (Oise), directed by M. Gall. Pure carbonic acid is there produced very economically by combustion of coke; is collected in a gasometer, from which it is drawn, to be dried and compressed with pressures of 5, 25, and 70 atmospheres, and stored in iron bottles. Most of the acid is used for making salicylic acid; but other applications occur, and M. Gall is increasing the power of manufacture. At present 300 kilogrammes are produced daily, but it will be possible ere long to produce 1000 kilogrammes. The liquid is now supplied in Paris at 60 c. the kilogramme (say 6d. for 2½ lbs.). Thus the French production is in a condition to compete with the German. Among other uses besides those already mentioned are the manufacture of aerated waters, the filtering of wine, cooling by virtue of the great absorption of heat in vaporizing, and solidification of fused metals under high pressure (which greatly improves the quality).

FROM a recent report on the telephone system in Belgium (which has grown rapidly since 1883) we learn that the State has considerably supplemented the work of the companies constructing and working various small lines, and using on all of them the double wire (while the companies have mainly continued the single one). The material used is the phosphorus bronze of Montefiore. The subscription varies largely, from 250 fr. in a radius of 3 km. in Brussels and Antwerp, to 125 fr. in Louvain and Malines. One interesting feature of the Belgium lines is that they are all connected with the principal telegraph offices, so that subscribers can send to these, by telephone, any telegrams they wish sent, and similarly they can receive telephonically any telegrams addressed to them. A copy of the telegram is sent at the same time. The number of telegrams thus sent by telephone in 1889 was 371,000; in 1890 it grew to 440,000. To facilitate the development of telephonic relations the country is divided by Government into a number of circles, containing several towns provided with central offices communicating with each other by means of a double wire. Thus the inhabitants of a small town like Heyst are able to speak with Bruges, Blankenburgh, Ostend, Middlekerke, and Nieuport. The system is being extended wherever clients are probable, and the telephone now enters largely into Belgian habits.

IN the south-east of the valley of Mont Dore (Puy-de-Dôme is a curious natural formation in the basalt, called the Creux-de-Souci. A crater-shaped depression about 80 ft. wide communicates by a central hole with a larger circular cavern, 170 ft. diameter, the bottom of which is occupied by a small lake with about 10 ft. of water. The shape is like that of two cups with bases opposed; the lower one the larger. From an examination of the place this summer by M. Martel and some friends (*La Nature*), it appears that carbonic acid is plentiful in the cavern. Several times they went down by rope-ladder, hoping to use a boat lowered previously; but they could not get below about 13 ft. from the water (which was about 70 ft. from the orifice); they experienced headache, progressive suffocation, &c., while matches and candles went out. The cavern is probably closed; there is no sign of a stream; nor are there any stalactites. The lake is merely fed by water filtering through the basalt; after heavy rain this is considerable. The temperature is exceptionally low, which M. Martel explains thus: Snow lies several months on the neighbouring ground, and when this melts in spring its water penetrates into the Creux-de-Souci at a temperature near 0°C. Thus the air is cooled, and, being denser than that outside it, accumulates below; it is not renewed from above. No air-current was observed. The accepted view that there is water communication with Lake Pavin (about 270 ft. lower) is considered a mistake. It would be interesting, M. Martel says, to make methodical observations, in different seasons, both as to the carbonic acid and the temperature.

MR. C. DAVIES SHERBORN asks us to state that the grant from the British Association, stated by us as being made towards "Index to Plants," &c., was really towards "Index Generum et Specierum Animalium," a work which has already been referred to on two occasions in NATURE—May 15, 1890, and July 2, 1891.

THE additions to the Zoological Society's Gardens during the past week include a Japanese Ape (*Macacus speciosus*, ♂) from Japan, presented by Mr. H. H. Jacobs; two Rhesus Monkeys (*Macacus rhesus*, ♂ ♀) from India, presented by Mr. R. Dodman and Mr. C. W. Emlyn respectively; a Macaque Monkey (*Macacus cynomolgus*, ♀) from India, presented by Mr. R. Rocca; two Crowned Lemurs (*Lemur coronatus*) from Madagascar, purchased; a Common Cormorant (*Phalacrocorax carbo*), British, presented by Capt. Salvin; two Spotted-sided Finches *Amadina lathami*) from Australia, purchased; twenty-five Cambayan Turtle Doves (*Turtur senegalensis*) from East Africa, deposited by General Mathews; three Cambayan Turtle Doves (*Turtur senegalensis*) from East Africa, presented by General Mathews; three Hardwickes Mastigures (*Uromastix hardwicki*) from India, purchased; a Robben Island Snake (*Coronella phocarum*) from South Africa, presented by Miss M. Rutherford; a Nilotic Monitor (*Varanus niloticus*) from East Africa, presented by Gen. Mathews; a Nilotic Monitor (*Varanus niloticus*) from East Africa, presented by Mr. Frank Finn, F.Z.S.; two Smooth-clawed Frogs (*Xenopus lævis*) from East Africa, presented by Mr. Frank Finn, F.Z.S.; a Common Boa (*Boa constrictor*) from South America, presented by Messrs. F. Sander and Co.; four Indian Wild Swine (*Sus cristatus*), born in the menagerie.

OUR ASTRONOMICAL COLUMN.

NOVA AURIGÆ.—In *Wolsingham Observatory Circular*, No. 33, it is stated that Mr. H. Corder having informed the Rev. T. E. Espin that the Nova Aurigæ had increased, it was examined August 21, and found to be 9·2, spectrum monochromatic; one intense line (500?).

THE OPPOSITION OF MARS.—At the Lick Observatory, up to the middle of August, many of the supposed canals on Mars discovered in 1877 by Schiaparelli were mapped, but none of them seemed to be double. On the night of the 17th inst., however, Profs. Schaberle, Campbell, and Hussey made three entirely independent drawings, each showing the canal marked Ganges on Schiaparelli's map to be distinctly double, and thus confirming in 1892 Schiaparelli's discovery of 1877.

THERMAL ABSORPTION IN THE SOLAR ATMOSPHERE.—In *Astronomische Nachrichten*, Nos. 3105–06, Mr. E. B. Frost sets forth the results of his observations with reference to thermal absorption in the solar atmosphere. As the paper is of considerable length, we will only concern ourselves with the broad results, leaving our readers to look up the details for themselves. The instrument—made by Mr. Frost himself, and used throughout the experiments—was a double thermopile, or, rather, two thermopiles, of considerable length; and the back junctions, after being carefully insulated and imbedded in sealing-wax, were inserted in the two ends of a brass U-shaped tube, the front faces of the piles projecting a little out of the tube, while their back parts were in contact in the middle. To ensure an equality of temperature at the two back junctions, this part of the tube was enveloped in a cylinder filled with water, thus eliminating practically accidental thermo effects in the metals of the thermopiles. Mr. Frost's original intention was to employ both these piles, one for receiving the projected image of the sun, and the other for the direct rays, but, as he became acquainted with the "disproportionately greater intensity of the latter," he was obliged to employ as a screen a thin silk gauze, thus using this pile as a counterpoise to eliminate such effects as air currents, reflected radiations, &c.

Let us deal first with the photosphere. The following table shows the differences between observation and theory. The column headed O is obtained from a curve based on the observations, that of C is the result of theory and gives the values of $I : I_0$ as obtained from the ratio $\frac{I}{I_0} = \frac{e^{-f \sec \theta}}{e^{-f}}$. ρ represents the distance of the point observed from the centre of the sun (radius = 100), and θ the angle at the sun's centre between the line to the observer and the radius to the point observed.

ρ	θ	O	C	C–O
0	0	100·0	100·0	0·0
10	5·7	99·9	99·8	– 0·1
20	11·5	99·4	99·3	– 0·1
30	17·5	98·4	98·4	0·0
40	23·6	96·3	97·1	+ 0·8
50	30·0	93·6	95·1	+ 1·5
60	36·9	89·8	92·2	+ 2·4
70	44·4	84·6	87·8	+ 3·2
80	53·1	77·9	80·6	+ 2·5
90	64·2	68·0	65·6	– 2·4
100	90·0	(39)	—	—

The differences in the last column might, as Mr. Frost says, be somewhat reduced by the introduction of another constant in the formula, but even then sufficient difference would remain to indicate the inability of the formula to cope with the present conditions.

In the attempt to ascertain whether there was a difference in the thermal conditions for the poles and the equator, taking points equidistant from the centre of the sun's disc, the conclusion Mr. Frost draws is that there is none. The difference between the two hemispheres also he finds "to be exceeding small, if real." With regard to the spots he says, "A rather surprising result of these observations was that spots are occasionally relatively warmer than the surrounding photosphere." Whether the position of the spot on the disc had anything to do with it is uncertain, but where the observations were referred to it was found that "the two spots with the highest relative temperature were very near the sun's edge." He further suggests that if further observation should establish this fact, viz., that spots suffer less absorption than the neighbouring photosphere, we might consider them "to be in a higher stratum than the photosphere."

HYDROGEN SPECTRUM IN THE SOLAR ATMOSPHERE.—M. Deslandres, in the *Comptes Rendus* for July 25, communicates a brief note concerning the spectrum of hydrogen that was photographed by him in a prominence on the 4th of May last. This spectrum, besides containing many metallic lines, shows also ten ultra violet radiations of hydrogen and five other new ones, the latter of which, as he says, follow so regularly the former series that one is led to consider them as due to hydrogen. It may be remembered that Mr. Balmer indicated a simple function of whole numbers which represented exactly the series of 14 radiations of hydrogen. This function, which is applicable to most of the metals, is $N = A - \frac{B}{n^2}$ where N is the number of vibrations, A and B two constants, and n a whole number. In the following table we give the result of M. Deslandres' measures with regard to the new addition to this series, to show how close an agreement exists between the calculated and observed values :—

Whole Nos. of the formula n.	No. of vibrations		
	Deslandres.	Ames.	Calculated.
12	266·565	266·575	266·566
13	296·685	267·715	267·694
14	268·585	268·615	268·586
15	269·310	269·330	269·309
16	269·890	—	269·898
17	270·385	—	270·387
18	270·795	—	270·797
19	271·140	—	271·142
20	271·460	—	271·448
21	271·700	—	271·694

REFRACTION IN MICROMETRIC AND PHOTOGRAPHIC MEASURES.—A very simple method by which the effect of differential refraction may be eliminated from the results of micrometric observations or from the measures of photographic plates is given by Dr. S. C. Chandler in the *Astronomical Journal*, No. 271. The principle underlying this method is the position of the plate about to be measured, which here is inclined at a certain angle in the vertical direction to the focal plane of the telescope. In the measurement of distances this inclination necessitates the application of a small correction, but this is soon accomplished by the aid of a simple formula, which can be considerably modified by determining the screw revolution directly from the plate. One might at first think that by this means the stellar images would be slightly affected, but Dr. Chandler informs us that he thinks that "attentive examination will show that the difference of definition will be inappreciable."

THE RECENT EARTHQUAKES.

THE first of the earthquake shocks felt on the 18th inst. in Ireland, Wales, and the West of England was evidently one of unusual strength for this country, and it is very desirable that both it and the subsequent slighter shocks should be thoroughly investigated, with a view to discovering their origin and their relations to one another. As I have been engaged for several years in working at our British earthquakes, and am now occupied in studying these recent shocks, I should be greatly obliged if you would allow me to ask your readers who felt the shocks for assistance in obtaining the necessary materials.

It would be of great service to know simply the names of as many places as possible where one or more of the shocks were felt and the accompanying sounds heard. With this knowledge the boundaries of the disturbed area and the sound-area of each shock may be determined—points of considerable importance. But for a complete study of the shock it is desirable to have further details, such as would be given by answers to the questions printed below, especially to those numbered 3, 4, 6, and 7. I shall be most glad and thankful to receive accounts of the earthquakes from any place whatever, and I may add that no account, however scanty the information given, can fail to possess some value or to help in throwing light on the nature and origin of the shock.

(NOTE.—If more than one shock was felt it is important that the notes relating to each should be kept separate.)

(1) Name of place where the shock was felt.

(2) Situation of the observer: (*a*) Whether indoors (and on which floor of the house) or in open air: (*b*) How occupied at the moment of the shock.

(3) Time at which the shock was felt, if possible, to the nearest minute.

(4) Nature of the shock, description of the: (*a*) The number of vibrations: (*b*) Their relative intensity: (*c*) Whether there was any tremulous motion before or after the principal vibrations: (*d*) Whether any vertical motion was perceptible, and if so, whether the movement was first upward and then downward, or first downward and then upward.

(5) Duration of the shock in seconds, not including that of the accompanying sound.

(6) Intensity of shock: Was it strong enough (*a*) to make windows, doors, fire-irons, &c., rattle: (*b*) To cause the chair or bed on which the observer was resting to be perceptibly raised or moved: (*c*) To make chandeliers, pictures, &c., swing, or to stop clocks: (*d*) To overthrow ornaments, vases, &c., or cause plaster to fall from the ceiling: (*e*) To throw down chimneys, or make cracks in the walls of buildings?

(7) Sound-phenomena: (*a*) If any unusual rumbling sound was heard at the time of the shock, what did it resemble? (*b*) Did the beginning of the sound precede, coincide with, or follow, the beginning of the shock, and by how many seconds? (*c*) Did the end of the sound precede, coincide with, or follow, the end of the shock, and by how many seconds? (*d*) Did the sound become gradually louder and then die away? (*e*) Were the principal vibrations felt before, at, or after the instant when the sound was loudest?

(8) The names of any other places where the earthquake was noticed would be most useful, together with answers for each place (if possible) to the following questions:—(*a*) Was the shock felt? (*b*) Was it strong enough to make doors, windows, fire-irons, &c., rattle? (*c*) Was any unusual rumbling sound heard at the time of the shock? CHARLES DAVISON.

38, Charlotte Road, Birmingham, August 23.

CHEMISTRY AT THE BRITISH ASSOCIATION.

AFTER the President's address, the first paper was read by Prof. Crum Brown on "Electrolytic Synthesis," descriptive of work carried out in conjunction with Dr. J. Walker.

He showed how, by an extension of the electrolytic methods which had been already fully worked out in relation to potassium acetate, the higher fatty acids of other series could be synthesised. Thus, starting from the ethyl potassium malonate the ether of succinic acid was obtained in considerable quantity and with great readiness. Similarly adipic, sebacic and other ethers had been obtained. Secondary products were formed which in the higher members of the series accumulated in inconveniently large quantities.

Professor Ramsay gave a communication on the "Impurities in Chloroform." He found that when the purest chloroform that could be prepared was exposed to light between the months of March and July, it emitted an acrid odour when opened, due to the formation of phosgene gas. The reaction by which this had been brought about was :—

$$2CHCl_3 + O_2 = 2\ COCl_2 + 2\ HCl.$$

The second day of the meeting was devoted almost entirely to the consideration of the phenomena accompanying the combustion of gases. Messrs. Lean and Bone gave an account of the results obtained in exploding ethylene with less than its own volume of oxygen. They had found that there was always a considerable rise of pressure, and that the resulting products contained, in addition to hydrogen and carbon monoxide, small percentages of carbon dioxide, unsaturated hydrocarbons, and some saturated hydrocarbon, presumably marsh gas.

The unsaturated hydrocarbons consisted largely, if not entirely, of acetylene. Carbon is also formed as a product of the reaction, due in all probability to the decomposition of heavy hydrocarbons into marsh gas and carbon at high temperatures. The experiments show that oxygen combines with carbon in preference to hydrogen.

Prof. Lewes, in his paper on the "Luminosity of Hydrocarbon Flames," described the results of the analyses of the gases drawn from an ordinary coal gas flame at different heights. He had found that the heavy hydrocarbons which occur in the non-luminous part of the flame are almost entirely converted into acetylene before they reach the luminous zone. The luminosity of the flame is, in his opinion, brought about by dissociation of the acetylene, the temperature required for this dissociation varing with the degree of dilution of the acetylene. Under the circumstances already described, where the amount of acetylene present was 1·1 to 1·3 per cent., the temperature was 1200°, whilst in the flame of a paraffin lamp, where about double the amount of acetylene was present, the temperature was found to be 1000°.

On passing ethylene through a heated tube at different temperatures he found that at 900° the chief products were methane and acetylene; at 1000° there was still no hydrogen and no carbon, but more oil and heavy hydrocarbons, whilst at a still higher temperature hydrogen and carbon appeared amongst the products; above 1200° there was much carbon and little or no hydrocarbons. The actual temperature of the gas flame used was 500° at a distance of half an inch above the burner; 1279° at the top of the non-luminous zone, and 1370° at the top of the luminous zone.

Prof. Smithells followed with a number of very beautiful "Experiments on Flame." He held that the ordinary candle flame showed four and not three zones as usually described. He considered that the phenomena of combustion in flames ought to be studied by using gases of simple and definite composition rather than a variable and complex mixture such as coal gas.

He showed, by means of experiments, the two distinct zones in the non-luminous Bunsen flame, and how these could be separated, and their character varied according to the amount of air admitted, and similar illustrations were given by burning a jet of air laden with benzene vapour. Under the conditions of the Bunsen flame he had found that whatever hydrocarbon was used the products withdrawn from the inner cone consisted of carbon monoxide, carbon dioxide, hydrogen, and water vapour, whilst in the case of the benzene flame described, when the air supply was so regulated as to produce a luminous zone between the inner and outer zones, acetylene was found amongst the gases withdrawn from that zone.

His experiments had led him to conclude that when the hydrocarbon is starved of oxygen the carbon burns preferentially to the hydrogen.

Prof. Smithells then introduced a spray of cupric chloride solution into the gas, and showed that the inner flame remained unaltered in appearance, whilst the outer flame became green.

He is of opinion that the decomposition of the salt takes place in the inner flame, and that the colouration of the outer flame is due to the projection of the products of decomposition through the outer flame. A discussion followed these papers, in which Sir G. G. Stokes described the experiments he had performed with a view to determine whether the luminosity of the flame was due to carbon or to hydrocarbons. He was not in favour of the idea that the colouration of the flame was due to chemical reactions taking place within it. Sir Henry Roscoe thought it due to the separation of metal in the flame, and not to the oxide. Prof. Liveing quoted the results of his observations on the spectrum of oxygen, and expressed his adherence to the hydrocarbon theory of luminosity. Prof. Ramsay supported Prof. Smithells' contention. The discussion came to a conclusion with the replies of the authors of the papers.

Dr. J. A. Harker then followed with a description of "The Reaction of Hydrogen with Mixtures of Hydrogen and Chlorine." He finds that as had been previously observed by Horstmann, Bunsen, and others, the hydrogen combines partly with the oxygen and partly with the chlorine, but that the reaction varies with the quantities of the constituent gases present, and takes place in accordance with the law of Guldberg and Waage.

Prof. Clowes gave the results of the investigations which he had taken up in order to produce a safety lamp which should indicate with greater accuracy the presence of inflammable gases and vapours in air. In confirmation of previous observations he had found hydrogen to be by far the most sensitive flame, and he described a means by which hydrogen could be burnt in an ordinary oil safety lamp with greater convenience than had hitherto been possible.

A discussion which was to have been held in conjunction with Section D on the "Chemical Aspects of Bacteriology," fell through.

Prof. Roberts Austen gave a paper on the "Effect of Small Quantities of Foreign Matter on the Properties of Metals." The addition of two-tenths per cent. of lead or bismuth to gold was found to render it quite brittle, whilst extremely small quantities of phosphorus, magnesium, and zinc made nickel malleable. Such phenomena had no doubt been of great interest in ancient times to the alchemist, but to-day they constituted all-important questions for the engineer. Experimenting on gold, which could be obtained more readily than most other metals free from impurities, either solid or gaseous, he found that the tenacity was decreased by the addition of small quantities of elements whose atomic volumes were greater than that of gold, whilst those elements whose atomic volume was the same or smaller than that of gold, increased its tenacity. Lithium and aluminium acted in an exceptional manner. Furthermore, whilst the addition of 10 per cent. of aluminium gave an alloy melting at 400° lower than gold, 23 per cent. of the admixture yielded a brilliant alloy having a higher melting point than gold. He pointed out also that gold during the process of cooling showed abnormalities similar to those shown by iron, which, however, disappeared when the operation was carried out under pressure. Prof. Hartley had found that iron required to be slightly oxidised before it could be melted, even at a temperature which sufficed to melt platinum. He had always found that silver and copper, unless prepared with special precautions which he described, contained gold.

Dr. Gladstone submitted a communication on the "Molecular Refraction and Dispersion of Metallic Carbonyls and of Indium, Gallium and Sulphur." The observations made on a sample of the iron pentacarbonyl supplied to him by Mond indicated an extreme dispersion for iron, even taking the highest value for carbonyl previously recorded. He attributed, however, a still higher value (11·2) to carbonyl, and assigned a chemical formula in accordance therewith. With regard to sulphur he had found that the values obtained varied only slightly, whether the sulphur was in the liquid, solid or gaseous condition. Prof. Liveing found that the same thing held for oxygen and nitrous oxide in the liquid and gaseous conditions, and considered that this pointed to the continuity of the gaseous and liquid states.

Dr. G. H. Bailey gave a paper on "Impurities of Town Air." He pointed out that the amount of air taken into the system daily greatly exceeded that of the liquid and solid food, whilst according to Tyndall expired air was very free indeed from solid particles, and that air was undoubtedly the medium by which many diseases were propagated, and that in towns, as a matter of fact, the death-rate rose to very abnormal proportions during those periods when the air was most polluted. Under these circumstances it was a matter of surprise that so little attention had been devoted in recent years to the determination of the impurities in air. A very large amount of information had, it was true, been obtained relating to the carbonic acid in air, and this had led to valuable results; but with the exception of Dr. Russell's extremely interesting reports, hardly anything had been done in the direction of determining the sulphurous acid and organic matter with which town air, especially at certain seasons, was laden. He then described the methods which had been adopted by the Air Analysis Committee of Manchester for determining these impurities, showing how it was not only possible to arrive at a measure of the amount of suspended organic matter, but also to ascertain proximately how far it was of a noxious character. Such analyses may appropriately be supplemented by a bacteriological examination of air. Some hundreds of analyses of the air of London, Manchester, and Liverpool had been made, and the following conclusions were drawn from them:—(1) That in clear breezy weather the amount of sulphurous acid in town air does not exceed one milliogramme per 100 cubic feet of air. (2) That in antiyclonic periods, and especially in times of fog, diffusion is seriously interfered with, and the quantity has been found as high as 50 milligrammes. (3) That the organic impurities in air also increase under similar conditions to those which promote the accumulation of sulphurous acid to 40 or 50 times their normal amount at least.

In the discussion which followed Sir Douglas Galton expressed himself well satisfied with the enquiry, and hoped that the work would be continued. He called attention to the tendency for decaying matter to collect, especially in certain areas of large towns and the danger of allowing such accumulations. Mr. A. E. Fletcher, Chief Inspector of Alkali Works thought the house fire was a large contributor to the evil and a most difficult one to contend against. He suggested filtering the air for the house through cotton wool filters and had found that it could be applied with great success. Mr. Warrington criticised the methods of analysis and would like to see the determinations extended so as to show in what quantity the respective sulphur compounds existed in the air. Dr. Rideal had found the method of determining sulphurous acid most reliable and preferable to the Gas Referee's test used for the estimation of sulphur in coal gas. Messrs. Hartog, Fairley, Thomas, Dr. Clowes and the President also spoke on the paper, and Dr. Bailey replied to various points which had come up in the discussion.

Subsequently, Prof. W. H. Perkin described methods of synthesis with the aid of butane and pentane tetra-carboxylic ethers the constitution of the methylene ring compounds being illustrated by Prof. Crum Brown by means of a very ingenious set of models.

A number of papers were carried over to the last day of the meeting mainly dealing with atomic weights and analytical work. Amongst these. Prof. Ramsay and Miss Aston contributed the atomic weight of boron (*a*) by determination of the water of crystallization in borax (*b*) by conversion of anhydrous sodium borate into sodium chloride. The value obtained was 10·966. Mr. Hartog drew attention to the results just published of a determination of the atomic weight of boron by the late Dr. Abrahall.

Prof. Ostwald read a communication on the assumed potential difference between metals in the solid and in the molten state. His experiments failed to detect any such difference of potential; it is at any rate below $\frac{1}{1000}$ of a volt. Prof. McLeod showed that the iodides of sulphur, SI_6 and S_2I_2, if they existed at all as chemical compounds, were of a most unstable nature; the only evidence of definite combination having taken place in S_2I_2 was that it melted at a lower temperature than either of its constituents.

BIOLOGY AT THE BRITISH ASSOCIATION.

SO many important and interesting papers were submitted to the Organizing Committee of D this year that it was found necessary to divide the section into the three departments of Zoology, Botany, and Physiology. The plan of adjourning for lunch at half-past one, and resuming work again at two, with some attractive papers for the afternoon, was tried and found a success. Practical demonstrations and exhibitions were also given in the afternoons in the laboratories above the lecture-room.

On Thursday, August 4, after the president's address, the following series of reports by committees appointed at the Cardiff meeting was submitted: (1) The Zoology and Botany of the West India Islands; (2) the Naples Zoological Station; (3) Zoology of the Sandwich Islands; (4) Botanical Laboratory at Ceylon; (5) Migration of Birds; (6) Plymouth Laboratory; (7) Deep-Sea Tow-net; (8) Protection of Wild Birds' Eggs. All of these committees have this year been re-appointed with or without grants. Three papers were then taken in the afternoon, viz.: (1) Renewed experiments on the modification of the colours of Lepidopterous larvæ, with exhibition of specimens, by E. B. Poulton, F.R.S.; (2) Prof. Preyer, of Berlin, on the physiology of protoplasm; and (3) Prof. Hartog on the alleged personality of the segments of the nucleus, and Weismann's "Idant" theory of heredity. Prof. Preyer attributed an important part to the absorption of oxygen by the protoplasm in the formation of pseudopodia. Prof. Hartog contended, from previously ascertained facts, and from his own recent researches, that the view that the segments that constitute the young nucleus persist during its maturity is untenable, and that Weismann's "Idant" theory of heredity being founded thereon must necessarily fail.

On Friday, in the Botanical Department, important papers were read by Dr. Scott (on Secondary Tissues in Monocotyledons), Prof. Goebel (on the Simplest Form of Mosses), Prof. Errera (Physiological Action at a Distance), Prof. Bower (Morphology of Spore-bearing Members in Vascular Cryptogams), and others; these will be noticed elsewhere.

In the Department of Physiology there were the following:—

(1) Prof. Waymouth Reid gave a paper on Vital Absorption, in which he showed that the older views of Dutrochet and others as to the process being a physical one due to osmosis must be modified in the direction of showing that the vital activity of the cells composing the absorbing membrane must be taken into account. We know that changes are wrought upon substances during the process of absorption, such as the regeneration of serum-albumen from peptone. In the case of the intestine of the rabbit in full digestive activity, one can get evidence of a stream passing from within outwards so long as the tissues are alive. Scraping off the epithelium diminishes the transfer or puts a stop to it. By the addition of pilocarpine to the fluids used, it is possible to reverse the direction of the stream.

(2) Prof. Rosenthal, of Erlangen, read a paper on Animal Heat and Physiological Calorimetry. The apparatus he made use of has an air calorimeter. In fever, produced by injection of putrid matter, he finds that heat production is not augmented; although in a few experiments he made on man he found a small augmentation of heat production.

(3) Dr. Lockhart Gillespie communicated a paper on Proteid-hydrochlorides, in which he stated that all proteids have an affinity for hydrochlorides, and the lower proteids combine with a greater percentage of HCl than the higher. These results were supported by the amount of silver which is contained in a series of the different proteid salts of silver, the ratio of silver to albumen being highest, and that of silver to peptone being lowest. The different stages of gastric digestion of a meal he finds to be:—1, the amylolytic stage—no free HCl being present, but some combined proteids—duration about ten minutes; 2, combined hydrochloric acid (proteid-hydrochloride)—acidity considerable, no free HCl, small amount of lactic acid present—duration about half an hour; 3, free HCl stage—some free HCl, but mostly combined, lactic acid disappearing; 4, the chief absorption stage—acidity falling, but proportion of free to combined HCl rising—from three to four or five hours; 5, evacuation—propulsion of contents of stomach into duodenum at fourth or fifth hour.

(4) Dr. E. W. Carlier gave an account of the hibernating gland of the hedgehog, which is situated along the cervico-dorsal and in the axillary regions, and attains its maximum dimensions in October—*i.e.*, just at the commencement of hibernation—and its minimum shortly after the animal has awakened from winter sleep. Histological examination shows that towards the close of hibernation many of the cells change. The chromation in the nucleus diminishes, the fat stored in the cell gradually disappears, and finally the whole cell breaks up. Dr. Carlier considers that the hibernating gland is not merely a storehouse for fatty matter, but actually secretes some nutritive material of great service to the animal during its winter sleep.

(5) Dr. G. Mann read a paper on the Functions, Staining Reactions, and Structures of Nuclei, in which he endeavoured to prove that the achromatic elements of a cell are the most important, and that the nuclear chromosomes are organs for the assimilation of food, while the centrosome is a trophic centre for the nucleus.

In the Department of Zoology, the following papers were read:—

(1) Dr. Henry C. McCook (Philadelphia), on the Social Habits of Spiders. This paper considered the claims of certain species of the Araneæ to possess in some degree the communal tendencies of the Social Hymenoptera. The eminent French araneologist, M. Eugène Simon, in his studies of South American spiders, finds a temporary sodality among certain orb-weavers (*Epeira Badelieri*) at the cocooning season, which Dr. McCook thought might be explained by the well-known fact that female spiders when cocooning often choose the same locality and mass their egg-bags, the one mother overlaying the cocoon of another. But this is quite incidental, and occurs with species which are known to be solitary. The close grouping of Simon's *Uloborus republicanus* was regarded as no proof of a sodality, but simply showed an assemblage of snares in proximity which is not uncommon. The gathering of males in groups on the outer lines of the webs is quite what one sees in other species with which there is no departure from the solitary habit. The third example of supposed social spiders (*Anelosimus socialis*) shows characteristics closely resembling those of young spiders of various genera, who will weave around themselves upon the foliage where they lodge a tent of delicate spinning work within which they dwell for a short space, and then scatter, every individual at once assuming the solitary habit. If Simon's observations be here confirmed, we shall have the transfer of this trait of young spiders in many species to the adult period of at least one species. The fact

would revolutionize our ideas of the universal prevalence of the solitary habit. The paper was illustrated with a number of large painted figures.

(2) Prof. A. Crum Brown, F.R.S., on a Use of the External Ear. The form of the external ear enables us to find the altitude of the source of sound by rotating the head about a horizontal right and left axis.

(3) Prof. Lloyd Morgan, the Method of Comparative Psychology. The object of this communication was to show that our interpretation of animal intelligence is necessarily based on a double or two-fold process of observation: 1st, the activities of animals have to be carefully observed as objective phenomena; 2nd, our own mental processes have to be carefully observed and cautious inductions drawn from them. Finally the objective phenomena reached by the first process have to be interpreted in terms of conclusions obtained through the second. In the higher animals there is abundant evidence of ability to sense or feel relations, but little or none of the perception or cognition of the relations of introspection or of reflection, and possibly herein we have a limit to animal intelligence.

(4) Mr. J. E. S Moore, on the Relationships and Rôle of the Archoplasmic Body during Mitosis in the larval Salamander. The author has extended the discovery of the archoplasmic body in the spermatocyte of the salamander to the somatic cells of both the larva and adult, and especially to the cells of the germinal blastema and the leucocytes. He demonstrated for this vertebrate a distribution and functional activity of the archoplasmic body identical with that recorded by Platner for the invertebrate *Helix*; and concluded that the archoplasmic body is the sole agent in the formation of the achromatin spindle-fibres.

(5) Prof. J. C. Stewart exhibited with remarks an abnormal fore foot of a horse, in which two large digits and vestiges of others were present.

(6) Dr. G. Mann read a paper on the Origin of Sex, in which he contended that any sexual cell might be transformed into either a male or female cell, according to the facilities of acquiring and assimilating food material.

(7) Dr. J. Beard, on Larvæ and their Relations to Adult Forms. The author attempted to show that all metazoa above cœlenterata developed through the intermediation of a larva (often disguised by the presence of food yolk), and, in fact, upon the latter. He urged that the recapitulation theory was no explanation of the phenomena of embryology; at best it held good to a limited extent for the ontogeny of certain organs. The views of the author led him to regard metazoon development as a sort of alternation of generations.

(8) Professor W. A. Herdman, F.R.S., on the Exploration of the Irish Sea to the south of the Isle of Man now being carried on by the Liverpool Marine Biology Committee.

On Saturday, August 6th, the section did not break up into departments. The following papers were read:—

(1) Prof. McKendrick, F.R.S., demonstrated by means of a new form of myograph a method of recording and projecting simultaneously upon a screen, through the aid of lime light, curves of muscular contraction. He also showed a method of measuring and recording the time occupied by short voluntary movements, such as those of the fingers in writing, or the movements of the tongue.

(2) Prof. G. Fritsch (Berlin), on the Origin of the Electric Nerves in the *Torpedo*, *Gymnotus*, *Mormyrus*, and *Malapterurus*. Prof. Fritsch pointed out that there are two kinds of electric organs found, the one being modified muscles, as is the case in *Torpedo*, *Gymnotus*, *Mormyrus*, and *Raia*, while the other belongs to the cutaneous system, and is probably transformed gland cells of the skin, as in *Malapterurus*. In electric organs originating from muscles there are many ganglion cells, but in those derived from skin organs there are only two ganglionic cells, one on each side, and only one nerve fibre belonging to each cell, which fibre is formed by a combination of protoplasm-processes at a certain distance from the gigantic ganglion cell.

(3) Prof. Miall, F.R.S, gave an account of the leaf of the water plant *Victoria regia*, illustrated by lantern slides, in which he described the peculiarities of its structure, and the way in which it is modified to suit its special environmental conditions.

(4) Dr. J. Musgrove, the Blood-vessels and Lymphatics of the Retina. The author pointed out that the distribution of the vessels in the retina was as regular as that occurring in the arm or the leg. The blood-vessels of the retina of the ox may be divided into three sets. There are upper and lower sets of branches of large vessels, and there is an intermediate zone entirely free from large vessels except in so far as it is traversed by the main stems of artery and vein in their course to the upper part of the retina. This intermediate zone the author regards as the homologue of the yellow spot found in the human retina. The capillary vessels on a transverse section of the retina are seen to lie chiefly in the nerve cell layer, the inner molecular layer, and the inner nuclear layer. Only rarely are capillaries found beyond the inner nuclear layer, and they never extend as far as the outer nuclear layer, so that the outer layers (the rods and cones, &c.) are entirely free from vessels.

(5) Mr. H. O. Forbes exhibited a recently discovered series of sub-fossil bones of extinct birds of New Zealand and the Chatham Islands, and made remarks upon the localities where they had been found and upon their distribution. From the Chatham Islands the specimens were in a remarkably fine state of preservation, and included the species described under the names of *Aphanapteryx hawkinsi*, *Fulica newtoni*, and *Corvus moriorum*, along with portions of *Nestor* and *Harpa*. From New Zealand, *Bizuira*, *Cereopsis*, *Cygnus*, and the type specimens of *Cnemiornis gracilis*, Forb., were exhibited, and also the larger part of the skull of *Harpagornis moorei*, Haast.

(6) Dr. J. Clark, on the Natural Relations between Temperature and Protoplasmic M ovements. The author showed that the minimum temperature for protoplasmic movements depended on the nature, habits, and natural surroundings of the plants, and that change of conditions of growth induced change of minimum.

(7) Dr. J. Clark, Experimental Observations on the Functions of the Nucleus in the Vegetable Cell. By divesting the vegetable cell of its wall, and also by mechanically separating the protoplasmic contents of a cell into two equal parts, the author tried to show the relations between the nucleus and cell-wall formation, and between mechanical stimulus and nuclear activity.

(8) Dr. Francis Warner, Co-ordination of Cellular Growth and Action by Physical Forces. The facts accumulated in a report on 50,000 children observed by the author appear to show that defects in development of the body are largely co-related with defects of the nerve system in its power of co-ordination and mental function.

(9) M. Louis Olivier, La Canalisation des Cellules et la Continuité de la Matière vivante chez les Végétaux et les Animaux. The author has for some time recognized, even in highly differentiated tissues, the canalization of the cell wall and the free passage of protoplasm; and lately he has obtained evidence, photographic and otherwise, that in highly organized forms, such as Dicotyledons, the protoplasm is continuous from the extremity of the roots to the tips of the leaves.

(10) Dr. John H. Wilson, some Albucas and their Hybrids. The author has formed crosses between hybrids and the parent forms in several species of the African liliaceous genus *Albuca*.

On Monday, Section D was occupied in the forenoon by a discussion on "Sea-Fisheries":—

(1) Prof. McIntosh, F.R.S., opened the discussion by a paper entitled "A Sketch of the Scotch Fisheries, chiefly in their scientific aspects, during the past decade, 1882-92," in which he gave an interesting account of the condition of the fisheries, and of the investigations which have been carried on by the Fishery Board of Scotland, and at the St. Andrews Marine Laboratory, and elsewhere.

(2) Prof. Ewart followed with a general paper on our sea-fisheries, in which he showed that some of our valuable fishes are becoming scarce, and discussed various remedial measures which have been suggested. He considered that fish-hatching was not of much practical use if the young were merely returned to the sea when hatched.

(3) Mr. E. W. L. Holt read a paper, drawn up by himself and Messrs. W. L. Calderwood and J. T. Cunningham, of the Marine Biological Association, on the Destruction of Immature Fish, and a discussion of remedial measures. In this paper the authors dealt chiefly with the protection of immature fish by the imposition of a size limit. It was contended that the size limits proposed at the conference at Fishmongers' Hall last February are altogether too small, and that no limit can be useful which is not based upon the size at which a fish is for the first time able to reproduce its species. Tables were given showing the variation which exists in this respect in the different districts. The authors gave figures showing the immense destruction of immature fish on certain grounds lying on the east side of the North Sea, and the opinion was expressed by Mr. Holt, who has had

charge of the Association's work in that district, that the imposition of a reasonable size-limit for plaice alone would do more to cause the trawlers to leave these grounds unmolested than could be effected by any scheme of closing based on international agreement.

Various zoologists and fishing experts, including Prof. Ray Lankester, Prof. McIntosh, Prof. Ewart, Dr. Fullerton, Mr. Olsen, Mr. Stebbing, Mr. Walker, and Prof. McKendrick, took part in the discussion which followed.

(4) Dr. W. Ramsay Smith, The Food of Fishes. This statistical paper gives the result of observations made by the naturalists of the Fishery Board for Scotland on over 10,000 food fishes collected in the Firth of Forth and St. Andrews Bay during the last four years. The author considers the statistics so extensive as to reduce the limit of the errors of observation to such an extent as to allow general conclusions of a trustworthy character to be drawn now for the first time.

(5) Mr. E. W. L. Holt, Notes on Teleostean Development.

(6) Mr. A. P. Swan, The Effect of Sea-water on the Vitality of the Salmon Fungus. The author showed that immersion in sea water even diluted with any lesser proportion than three parts of fresh water is fatal to the fungus; and from the continuous nature of the hyphæ it is certain that the disease is destroyed on the stay of the fish in the sea, and that the recurrence of the disease on the return to fresh water must be due to re-infection. In the discussion that followed Mr. George Murray expressed his acceptance of the author's results.

(7) Prof. E. G. Prince, on the Formation of Argenteous Matter in the Integument of Teleosteans. The fibrillated substance to which the integument of many fishes owes its silvery lustre is formed in a layer of granular plasma which belongs to the mesoderm.

(8) Prof. E. E. Prince, The Development of the Pharyngeal Teeth in the Labridæ. The grinding plates in the pharynx of wrasses are developed from rounded dental sacs formed from the cells of the mucous layer.

(9) Dr. Carlier, on the Skin of the Hedgehog. The skin of the dorsal surface is very thick, and very rugose. The spines spring from depressions between the rugosities. On section the mucosa is very thick, and devoid of blood vessels except beneath. Sweat and sebaceous glands are absent: radiation of heat is thereby almost prevented. The spines which are morphologically hairs, are fixed in the cutis vera by a broad base, near which is a rich capillary plexus. The spines, consist of cuticle, cortex, and medulla. The cortex is strengthened internally by twenty-two or more longitudinal septa. The medulla is divided into loculi by transverse imperforate septa, which divide at their margins into secondary septa, which again divide into tertiary, enclosing respectively secondary and tertiary loculi. The erector pili is very large, and somewhat fan-shaped. The skin of the ventral surface is much thinner, and is covered with soft hairs between which and the spines there is a gradual transition on the flanks. Sebaceous and sweat glands are present, and also much adipose tissue, and a thin skin muscle.

(10) Rev. Alex. S. Wilson, on the Industry and Intelligence of Insects in relation to Flowers.

(11) The following demonstrations were also given:—Dividing Pollen Mother Cells, by Prof. M. Hartog; Hibernating Gland of Hedgehog, by Dr. Carlier; Variations in Arrangement of Feathers in Wings of Birds, by Mr. Goodchild; Embryo-sac of Angiosperms, by Dr. G. Mann.

On Tuesday, Aug. 9, the Section again separated into Departments. In the Botanical Department, papers were read by Prof. Schmitz (Knöllchen am Thallus einiger Florideen), Mr. Carruthers (on the Structure of the Stem of a typical Sigillaria), Mr. T. Hick (on Calamostachys Binneyana), Mr. A. C. Seward (on Myeloxylon from Millstone Grit and Coal Measures), Prof. Hillhouse (Disappearance of native Plants from their local Habitats), and others which will be noticed elsewhere.

Mr. G. Murray drew attention to a comparison of the Marine Floras of the warm Atlantic and Indian Ocean, his remarks being illustrated by a printed table of statistics. He dealt with the question whether since the last period of a warm climate at the Cape when the two tropical marine floras mingled, the genera and species had had time to vary much, or remained the same in the warm Atlantic and Indian Oceans now separated by the colder flora at the Cape.

Mr. Harold Wager read a paper on the Structure of *Cystopus candidus*, a fungus found parasitic on the shepherd's purse. He pointed out that the nuclei are similar in structure in many respects to the nuclei of higher plants. In the formation of the oospore a number of nuclei are restricted to the periplasm, and at a late stage a number of nuclei are found in the oospore surrounding a large central oil globule. During fertilization the protoplasm and nuclei contained in the antheridium pass over into the fertilizing tube, but whether any of the contents pass into the oospore was not determined.

A paper, by Mr. James Britten, was read protesting against certain proposed changes in Botanical nomenclature.

Two papers were given by Prof. G. Gilson (Louvain), on the Affinity of Nuclein for Iron and other substances, and a Method of Staining Nuclei by Chemical Means. It is now certain that dead nuclein, as well as other substances found in the cell, have a strong affinity for the various compounds of iron and of other metals and negative chemical bodies. Thus the difficult question arises, Is the presence of iron in the nuclear elements constant and normal during life, and is this metal necessary for the chemical activity of the nucleus?

Dr. C. H. Bailey, Manchester, discussed the conditions affecting plant life in a town atmosphere, especially the falling off in the amount of light received, and the increase in sulphurous acid. Finally, a paper was read by Dr. G. Mann, which contended that the view first put on record by the author, viz., that the embryo-sac of Angiosperms corresponded to a sporocyte, and not a macrospore, was confirmed by the observations of Guignard, Dodel, and Overton, and that the eight cells within the embryo-sac were eight female sexual cells corresponding to the eight male sexual cells derived from a pollen mother-cell.

In the Department of Zoology the following papers were read:—

(1) Baron Jules de Guerne, Présentation de Planches inédites de Zoologie concernant les Recherches du Yacht *l'Hirondelle*.

(2) Baron Jules de Guerne, Crustacés Copepodes des Eaux sursaturés de Sel de la France et des Canaries.

(3) Dr. Arthur Robinson, Observations on the Development of the Posterior Cranial and Anterior Spinal Nerves in Mammals. At an early stage (eleven protovertebral somites) a continuous cord of nerve cells extends backwards from just within the posterior part of the auditory depression along the dorso-lateral angle of the medulle and spinal cord. At the time of formation of the secondary optic-cup this cellular cord loses a connection it had with the dorsal extremity of the neural tube, thickens between auditory vesicle and first somite, remains relatively small from first to fourth somite, and beyond the fourth somite gives origin to a series of swellings, the spinal ganglia. The ganglionic enlargement in the presomitic region becomes the root-ganglia of the glosso-pharyngeal and vagus nerves. An enlargement in relation with the fourth somite becomes the first cervical ganglion. Other enlargements in second and third somites become connected either with spinal accessory or (in cat) with posterior root of hypoglossal nerve.

(4) Prof. J. C. Ewart, on the Cranial Ganglia. The author discussed chiefly the ganglia of the glossopharyngeal and facial nerves in elasmobranch fishes, and their relations to the branches of the cranial nerves.

(5) Prof. W. A. Herdman, F.R.S., gave two short notes, one on the Geographical Distribution of Ascidians, in which he drew attention to the great predominance of species and individuals, and also of gigantic specimens in Arctic and in Antarctic seas; the other on the Presence of Atrial Tentacles in various genera of Tunicata, with a suggestion as to their function. The various forms in which up to now atrial tentacles have been found are phylogenetically rather closely related, and most of them are species in which the animals are in the habit of living closely aggregated together. Possibly under these crowded conditions it is an advantage to the animals to have the power (as some have) of reversing the usual current of water, or of using the atrial for a time as the inhalent aperture, when the atrial tentacles would have important functions to perform.

(6) Mr. E. B. Poulton, F.R.S., gave two interesting exhibitions of series of specimens, the one illustrating renewed experiments on the modifications of the colours of Lepidopterous pupæ, and the other being an observation bearing on the non-transmission of characters acquired by certain pupæ.

(7) Dr. J. Symington, on the Cerebral Commissures in the Marsupialia and Monotremata. The author held that in these two divisions of the Mammalia the Corpus Callosum was absent, the only transverse fibres that exist being those known as the

hippocampal commissure and the anterior commissure. These results support the conclusions of Owen, and are opposed to those of Flower.

(8) Prof. J. Playfair McMurrich, the Early Development of the Isopods. The author described the structure and mode of segmentation of the typical centrolecithal ovum of the Isopod *Jæra*, calling attention to the early differentiation of the germ layers, which may be traced back to the eight-celled stage. The mesoderm forms at first a band of cells surrounding the embryo, and later concentrates towards the ventral surface to form the blastodisc, behind which is the endoderm, these two layers becoming later enclosed by the ectoderm, which grows back over them by teloblastic proliferation.

(9) Dr. J. Beard gave some notes on Lampreys and Hagfishes.

(10) Prof. G. B. Howes and Mr. J. Harrison, on the Skeleton and Teeth of the Australian Dugong. The authors described the process of vertebral-epiphysis formation, showing that epiphyses, so far as represented, are formed late, and are rapidly merged into the substance of the vertebral body. They described the formation of structures which might, perhaps, be regarded as anticipatory of supernumerary phalanges, and pointed out that their observations lent no support to Kukenthal's view of the epiphysial nature of such phalanges. Five mandibular teeth were found to be present in the anterior region of each ramus in the manatee, and one of these they claimed as a canine. They recorded the discovery of milk predecessors to the first upper and the four lower incisors (?) of the dugong, and of the two anterior mandibular cheek teeth of the manatee; and discussed the bearings of these facts on the inter-relationships and affinities of the order Sirenia.

(11) Dr. H. C. McCook—Can Spiders Prognosticate Weather Changes? Dr. McCook first stated briefly the widespread popular opinion that spiders fairly indicate the weather by ceasing to spin before foul weather, and weaving freely before fine weather. He then gave a few extracts from his journal of observations on this point extending over six years, the tenor of which is that the popular opinion has no basis in fact. Many species of orb-weavers, which were colonized and kept under close observation, made snares freely before rains and storms, frequently even in the intervals between heavy rains.

(12) Mr. G. Swainson, some Notes on Marine and Freshwater *Chironomus*.

(13) Rev. Hilderic Friend, on British Earthworms. The author distinguishes between the four genera—*Lumbricus*, *Allolobophora*, *Allurus*, and *Dendrobæna*—to which British earthworms belong, and gives an account of the different species, some of which are new to science.

(14) Mr. H. Newman Laurence, the Human Body as a Conductor of Electricity.

(15) Prof. J. B. Haycraft, Fertilization of the Eggs of the Stickleback.

The two following papers, also on the programme, were taken as read:—

(16) Prof. Emile Yung, la Fonction Dermatoptique chez le Ver de Terre, and

(17) M. J. Richard, Note sur l'Œil Latéral des Copepodes du genre Pleuromma. The lateral eye in *Pleuromma* is variable in position, but is more often on the right side than on the left, and seems more constant in males than in females.

The following demonstrations were also given during the afternoon:—The Formation of Pearls (by Mr. Albert F. Calvert), Interesting British Food Fishes (by Mr. E. W. L. Holt), and the Structure of *Myeloxylon* (by Mr. A. C. Seward).

GEOGRAPHY AT THE BRITISH ASSOCIATION.

THE work of the Geographical Section was overtaken in four meetings, the large attendance at which was evidence that the papers read met at least with popular approval. It is more satisfactory to gather from the opinions expressed by specialists that many of the papers were solid and original, and that from the scientific standpoint the average work was of high excellence. Without doubt the most important of the new results announced to the Section was Dr. Schlichter's admirable development of a photographic process for determining longitude by the almost disused method of lunar distances. The practical value of the invention is very great, especially with regard to the mapping of partially known continents.

Like all other departments of the Association, Section E owed much of its success to the distinguished foreigners who took part in its proceedings. The papers by the Prince of Monaco and the occasional remarks of Baron von Richthofen were much appreciated. Two ladies read papers, Mrs. Bishop recounting her adventures on the borders of Tibet with her well-known literary grace, and Mrs. Grove giving a short, bright account of the rainless regions of Chile.

Prof. James Geikie's presidential address, although based entirely on geological reasoning, was truly geographical in so far as it utilized geology only for the purpose of explaining the origin of the existing surface conditions of the globe. As presenting the only sound basis of physical geography, this opening address proved to be one of the best and most original with which Section E has ever been favoured. Unfortunately, Prof. Geikie was prevented by illness from presiding at all the meetings, but his place was taken by the vice-presidents, Colonel Godwin Austen, Mr. H. J. Mackinder, Mr. E. G. Ravenstein, and Mr. Coutts Trotter.

The First Ascent of Oraefa Jökull.—In the absence of the author, Mr. J. Coles read an account by Mr. F. W. W. Howell of the first ascent of Oraefa Jokull in Iceland. Mr. Howell succeeded in making the ascent on August 12 last year, after several previous failures. Although only 6550 feet in height the mountain presented remarkable difficulties on account of the irregularity of the ice.

Place Names.—Dr. J. Burgess, in the course of a paper on place names, urged a uniform system of transliteration from Oriental alphabets as more scholarly and more satisfactory than any attempt to represent the sound of names phonetically. In no other way could uniformity of spelling be arrived at, and the diverse spellings now in use made the study of Asiatic geography in particular very toilsome and irritating. With regard to Gaelic names there were several serious errors in spelling on the ordnance map, but at the suggestion of Sir Charles Wilson a Committee of the Royal Scottish Geographical Society had taken the matter up, and aided by local committees were introducing important corrections. A lively discussion followed the reading of this paper, in which Sir Charles Wilson, Mr. Mackinder, Prof. Thomas Smith, and others took part. A Committee of the Association was formed to co-operate with the Scottish Society, and received a small grant to aid in the thorough revision of the orthography of Gaelic place names.

Effects of Rainfall in Formosa.—Mr. John Thomson, of London, gave an account of the effect of rainfall on the scenery of Formosa, illustrated by a number of fine photographs. The situation of the island and its mountainous structure conspire to give prominence to the effect of rain-action; the wind blowing in from the warm current of the *Kuro Siwo* strikes against a mountainous ridge which runs the whole length of the island and culminates in a summit 12,000 feet high. The mountain side to windward is scored with deep ravines, and the streams choked with huge boulders in course of transport to the coast-plains, which are deeply covered by fine alluvium washed down from the heights.

The Windings of Rivers.—Mr. J. Y. Buchanan, in a short paper, discussed the windings of rivers from the standpoint of hydrodynamics.

Lesser Tibet.—Mrs. Bishop (Miss Isabella Bird) described a journey undertaken in 1889, on the borderland of Tibet, which she approached from Leh, in Kashmir. The intensity of radiation at great altitudes, giving very hot days and cold nights, was observed to lead to a very rapid disintegration of the rocks, resulting in the formation of immense fields of gravel. Although presenting a vivid picture of the topography and scenery of the trans-Himalayan borderland, Mrs. Bishop entered more fully into the characteristics of the people, contrasting the false, suspicious, and cringing natives of Kashmir with the truthful, trustful, and independent people of Tibet, who always welcomed her warmly and dealt with her fairly.

The North Atlantic.—The Prince of Monaco read two papers on his oceanographical work, the first bearing on his experiments with floats on the surface circulation of the Gulf Stream, and its associated system of currents. About 10 per cent. of the floats thrown over from the Prince's yacht have been recovered, and by taking into account the position in which they were found and the date, important confirmation of the theoretical system of circulation was obtained. The current was found to be a circular whirl, with its centre a short distance south-west of the Azores. Floats thrown over near the centre were not recovered for many years, but those launched to the north or the south were thrown ashore more speedily on the coast of France, Spain, Portugal, North Africa, or in the West Indies. The only escape from the whirl was the Gulf-Stream drift towards Norway and the Arctic Sea. The mean rate of circulation was calculated as about 4½ miles per day, and the rate of movement was found to be more rapid in the western than in the eastern half of the whirl. The Prince's second paper set forth the advantages which would accrue to meteorology and to navigation if the atmospheric conditions of the North Atlantic could be observed and telegraphed daily to Europe. He pointed out that the Bermudas, the Azores, Madeira, the Canaries, and the Cape Verd Islands were, or would very soon be, in telegraphic communication with Europe. If high and low level observatories were established in these islands it would be possible to construct very fair synoptic charts of the North Atlantic, and vastly improve upon the useful Pilot Charts now compiled by the Washington Weather Bureau. The Prince was willing that all observations should be collected at Monaco, where the Government of the Principality would discuss and publish the data, and he suggested that the Governments most interested should send delegates to a conference to be held next winter at Monaco in order to discuss the feasibility of the scheme. Dr. A. Buchan, in commending the Prince's suggestions, said that the surface temperature of the North Atlantic had been proved to have an influence on the direction of cyclones crossing it, and consequently on the weather of the British Islands and western Europe. He thought a properly equipped low-level station on the Bermudas was the first desideratum; then a similar station on the Azores, to be followed by a high-level observatory. The results at Ben Nevis warranted the expectation of great advances, not only in knowing the weather of the Atlantic, but in forecasting weather for Western Europe, if the Prince's scheme received the encouragement which it deserved.

Detailed Oceanography and Meteorology.—Mr. J. Y. Buchanan described his observations on the temperature and density of the water in the Gulf of Guinea in connection with the counter-equatorial current. Dr. H. R. Mill gave a brief account of the physical geography of the Firth of Forth, dwelling particularly on the relation between tidal and solar variations of temperature in the water. The puzzling fact that in the Firth of Forth the water at high tide is saltest when that phase occurs in the afternoon was explained by the high water of spring tides occurring at that hour. Mr. H. N. Dickson, in a short paper, urged the claims of meteorology as a subject of instruction with special regard to its place in physical geography.

The Desert of Atacama.—Mrs. Lilly Grove, of Oxford, gave a vivid description of a journey through the Atacama desert, including a trip by rail from Antofagasta to Uyuni at an elevation of 13,000 feet in the Andes.

Photography and Surveying.—Colonel Tanner explained the system of photographic surveying which he has developed on the Himalayan survey. By the use of a finely ruled grating the angular intervals between prominent objects could be estimated, and in cases where detailed triangulation was impracticable very fair maps could be compiled from photographs taken from several prominent centres.

Determination of Longitude by Photography.—Dr. H. Schlichter communicated a most important paper, summing up a long series of experiments, and an investigation of the mathematical formulæ required in calculating longitude from lunar distances. His method enables him in favourable circumstances to fix the longitude to within 6″, an approximation hitherto only possible by telegraphic time comparisons. His summary is as follows:—

"Lunar distances as a means for the strictly accurate determination of geographical longitudes have been little used of late, partly on account of the splendid chronometers with which ships are now provided, and partly owing to the inaccuracies of the instruments commonly employed for lunars. For exploring expeditions on land, however, chronometers are of little value, and the other astronomical phenomena which may be used besides lunar distances are either too difficult for accurate observation by the majority of travellers, or occur too seldom, or are not accurate enough. The author therefore introduces a new method of observation and measurement of lunar distances, viz. by obtaining a parallel series of photographs of the moon and a fixed star or planet on one plate, and afterwards measuring the distances on the plate. For the elimination of all possible inaccuracies of the photographic film or of the lens, the lunar distances thus registered are checked by repeatedly photographing on the same plate two fixed stars, the positions of which are given in the *Nautical Almanac*, and the angular distances of which can easily be computed therefrom. The angular distances of the photographic lunars are then found by a simple proportion. The time for taking a set of eight photographic lunars on one plate does not exceed three or four minutes, and micrometric measurements show with perfect accuracy the change of the lunar distances (owing to the movement of the moon) during each interval of the eight observations. The minute accuracy of the method is hereby established. The micrometric measurements on the plate are made by means of the same *réseau* which is employed by the principal observatories for stellar photography, and the measurements may therefore be regarded as absolutely correct. Results thus obtained give the correct longitude of the place of observation. The author proposes to use this method for scientific expeditions into the interior of continents, &c., as well as for the further determination and correction of secondary meridians in navigation. For both purposes it is especially adapted on account of its minute accuracy and great simplicity."

African Travels.—The whole of one day was devoted to the reading of papers bearing on Africa, almost all having reference to South Africa. Mr. E. Wilkinson described two journeys which he had made in the Kalahari Desert. Mr. Theodore Bent summarized in an interesting manner the results of his explorations at Zimbabwe; a paper on the orientation of which was also read by Mr. Swan. In the report of the committee appointed to assist in the exploration of Zimbabwe, it was announced that Mr. and Mrs. Bent intended to pursue their investigations into African ruins of the Zimbabwe type in Abyssinia. Mr. John Buchanan gave an account of the industrial resources of Nyasaland, which his long experience there enabled him to do with authority. The fertility of the soil, and the intelligence and willingness to work of the people, were advantages common to few parts of tropical Africa. A staple commodity was still wanting, but there were unmistakable signs that this would before long be found in coffee, which has been grown with great and increasing success. Firm government of the country, the absolute suppression of the slave-trade, and of intertribal wars, were almost certain to result from the recent extension of the British protectorate; but the problem of communication remained as a bar to the effective development of the country. With really free traffic on the Zambesi and lower Shire, and a railway, or at least a steam tramway, on the new road from Chilomo to Lake Nyasa, the success of Nyasaland commercially would be assured. Lieutenant Crichton-Browne gave a popular account of a recent journey to Lobengula's capital, and of an interview with that monarch. At the close of this paper Mr. Joseph Thomson, whose health is still in a very unsatisfactory state, made a few remarks, the first he has been able to make in public since his return invalided from Africa a year ago. Dr. A. H. Hallen described the Haussa country, in the language of which he is specially interested. He hopes to be able, under the auspices of the recently-founded Haussa Association, to proceed to the western Sudan, and continue his studies in the country itself. Mr. Ravenstein submitted the report of the Committee on African meteorology, of which Mr. Symons, F.R.S., was secretary. The Committee has collected a considerable number of unpublished records of meteorological observations in tropical Africa, and has charged itself with exercising a friendly influence over existing stations and the equipment of new stations likely to promote a better knowledge of the climatological conditions of the continent. Instructions of an eminently practical kind have been drawn up, and by the circulation of these and the grant of sets of instruments to suitable observers, it is hoped that the special difficulties of tropical observing may be overcome. The committee has been reappointed, with the addition of Dr. H. R. Mill as secretary.

Proposed New Map of the Globe.—Mr. E. G. Ravenstein explained Prof. Penck's scheme of a new map of the world, on the scale of 1 to 1,000,000, or about sixteen miles to an inch. It was proposed to draw each sheet on an independent projection, the sheets embracing 5° in each direction, except those for latitudes higher than 60°, which would have a width of 10° of longitude. The map would be contoured at 100, 300, 500, and 1200 metres, hills would be printed in brown, and rivers in blue. The official spelling of all names written in the Roman alphabet would be adhered to, accepted names in other alphabets would be transliterated on a system to be afterwards agreed on, and names in unwritten languages would be rendered phonetically. The land surface of the globe would be represented in 769 sheets, and on an edition of 1000 copies it is estimated that there would be a deficit of over £100,000 if the sheets were sold at 2*s.* This sum would require to be subscribed by the Governments interested, or by private individuals. The practicability of such a map is proved by the fact that Mr. Ravenstein has himself produced with the aid of the Royal Geographical Society 46 five-degree sheets of a map of Africa. The utility of the new map is universally conceded.

Recent Travels.—Mr. Walker Harris described an adventurous journey through Yemen in the early part of this year, during a rebellion of the Arabs against the Turks. In spite of many difficulties, including imprisonment by the Turkish authorities, Mr. Harris succeeded in reaching Sanaa from Aden, and found the country to be well watered, of magnificent fertility, and by no means badly cultivated.

Mr. Coutts Trotter summarized the recent advances in the exploration and organization of British New Guinea.

Mr. H. O. Forbes described a visit to the Chatham Islands, where he discovered the bones of a remarkable flightless bird, identical with an extinct species also found in New Zealand, which is separated by 450 miles of deep water. The inevitable inference is that a land connection must formerly have existed between the two groups of islands. The importance of a careful search for similar remains in other islands of the southern hemisphere in the light of geographical distribution and speculations as to former lands is obvious.

Mr. W. R. D. Beckett, of the British Consular service in Siam, was the first Englishman to descend the Mekong river from the Eastern Laos States to Saigon, and described the various incidents of his adventurous journey.

Mr. C. W. Campbell, of the British Consular service in China, described his journey through Northern Korea, reporting favourably on the people as compared with the Chinese in their treatment of strangers.

Other Papers.—Prof. P. H. Schoute brought forward a new scheme for draining the Zuyder Zee, and Mr. Yule Oldham, lecturer on geography at Owens College, recalled attention to the early discoveries of Cadamosto on the west of Africa in the fifteenth century.

Sub-section on Chemical Oceanography.—A joint meeting of Sections B and E was held under the presidency of Mr. Buchanan for the consideration of a series of papers on oceanography. Mr. Buchanan communicated the result of some observations of the density of the water at a depth of 2000 fathoms off the coast of South America made by Captain Thomson, of the telegraph ship *Silvertown*. They are held to demonstrate that the deep water there has come direct from the Antarctic Sea. Prof. Pettersson gave a detailed and elaborate paper on the hydrography of the Kattegat and Baltic, illustrated by numerous special maps. Observations were made simultaneously at a number of points in the Baltic and its approaches; samples of water were preserved in sealed tubes for estimation of gases, and the density was in all cases measured on shore by means of Sprengel's pyknometer. The excess of precipitation over evaporation was found to cause an outflow of comparatively fresh water and a progressive decrease in the salinity from the Skagerrak inward. The fresh Baltic stream flows close round the coast of Norway as it escapes into the Atlantic. An undercurrent of salt water inward takes place, partly by reaction and partly by the rising up of the deeper layers against the ridges which divide the Baltic area into basins. This action is not uniform, but occurs by successive impulses and pauses. The physical boundary between the North Sea and the Baltic is not in the Belts, but along the ridge joining Rügen and Felster. The great mass of Baltic water from Rügen to the Gulf of Finland is of uniform salinity; it grows salter toward the North Sea, and freshens rapidly in the Gulf of Bothnia. In this region of uniform salinity temperature appears to be the chief cause of circulatory movement. By winter cooling a layer of intermediate minimum temperature is usually formed, in which flakes of ice may be produced that rise to the surface and consolidate there. Indications derived from observations fourteen years apart point to a partial or complete stagnation of the water in the deeper parts of the Baltic basin. The fresh Baltic stream is felt in summer far to the north along the Atlantic coast of Norway, but in winter it is greatly reduced, and comparatively warm North Sea water (4° to 6° C.) comes into the Skagerrak. This influx is coincident with the commencement of the great herring fishery, which comes to an end when the cold Baltic outflow is re-established in spring.

Dr. Andrussoff, of St. Petersburg, summarized the results of the recent Russian investigations on the Black Sea, the most remarkable discovery being the fact that below the depth of 200 fathoms the great mass of the water is stagnant, and so highly charged with sulphuretted hydrogen that all life is impossible.

Each paper was followed by animated discussion, in which Dr. John Murray, Dr. Buchan, Prof. Hartley, Dr. J. Gibson, Mr. Irvine, and Dr. H. R. Mill took part.

THE AMERICAN ASSOCIATION, PRESIDENT'S ADDRESS.[1]

A DIVISION of science has a work of its own to do, a work that well might be done for its own sake, and still more must be done in payment of what is due to the other divisions. Each section of our Association has its just task, and fidelity to this is an obligation to all the sections. Those engaged in any labour of science owe a debt to the world at large, and can be called to give an account of what they are doing, and what they have to do, that the truth may be shown on all sides.

If it be in my power to make the annual address of this meeting of any service at all to you who hear it—in your loyalty to the Association—I would bring before you some account of the work that is wanted in the science of chemistry. Of what the chemists have done in the past the arts of industry speak more plainly than the words of any address. Of what chemists may do in the future it would be quite in vain that I should venture to predict. But of the nature of the work that is waiting in the chemical world at the present time I desire to say what I can, and I desire to speak in the interests of science in general. The interests of science, I am well assured, cannot be held indifferent to the interests of the public at large.

It is not a small task to find out how the matter of the universe is made. The task is hard, not because of the great quantity in which matter exists, nor by reason of the multiplicity of the kinds and compounds of matter, but rather from the obscurity under which the actual composition of matter is hidden from man. The physicists reach a conclusion that matter is an array of molecules, little things, not so large as a millionth of a millimetre in size, and the formation of these they leave to the work of the chemists. The smallest objects dealt with in science, their most distinct activities become known only by the widest exercise of inductive reason.

The realm of chemical action, the world within the molecules of matter, the abode of the chemical atoms, is indeed a new world and but little known. The speculative atoms of the ancients, mere mechanical divisions, prefiguring the molecules of modern science, yet gave no sign of the chemical atoms of this century, nor any account of what happens in a chemical change. A new field of knowledge was opened in 1774 by the discovery of oxygen, and entered upon in 1804 by the publications of Dalton, a region more remote and more difficult of access than was the unknown continent toward which Christopher Columbus set his sails three centuries earlier. The world within molecules has been open for only a hundred years. The sixteenth century was not long enough for an exploration of the continent of America, and the nineteenth has not been long enough for the undertaking of the chemists. When four centuries of search shall have been made in the world of chemical formation, then science should be ready to meet a congress of nations, to rejoice with the chemist upon the issue of his task.

It is well known that chemical labour has not been barren of returns. The products of chemical action, numbering thousands of thousands, have been sifted and measured and weighed. If you ask what happens in a common chemical change you can obtain direct answers. When coal burns in the air, how much oxygen is used up, can be stated with a degree of exactness true to the first decimal of mass, perhaps to the second, yet questionable in the third. How much carbonic acid is made can be told in weight and in volume with approaching exactness. How much heat this chemical action is worth, how much light, how much electro-motive force, what train-load of cars it can carry, how long it can make certain wheels go round,—for these questions chemists and physicists are ready. With how many metals carbonic acid will unite, how many ethers it can make into carbonates, into what classes of molecules a certain larger fragment of carbonic acid can be formed, the incomplete records of these things already run through a great many volumes. These carboxylic bodies are open to productive studies, stimulated by various sorts of inquiry and demands of life. Such have been the gatherings of research. They have been slowly drawn into order, more slowly interpreted in meaning. The advance has been constant, deliberate, sometimes in doubt, always persisting and gradually gaining firmer ground. So chemistry has reached *the period of definition*. Its guiding theory has come to be realized.

---

[1] Address by Prof. A. B. Prescott, the retiring President, delivered at the Rochester meeting of the American Association for the Advancement of Science, August, 1892.

"The atomic theory" has more and more plainly appeared to be the central and vital truth of chemical science. As a working hypothesis it has directed abstruse research through difficult ways to open accomplishment in vivid reality. As a system of knowledge, it has more than kept pace with the rate of invention. As a philosophy, it is in touch with profound truth in physics, in the mineral kingdom, and in the functions of living bodies. As a language it has been a necessity of man in dealing with chemical events. Something might have been done, no doubt, without it, had it been possible to keep it out of the chemical mind. But with a knowledge of the primary elements of matter, as held at the beginning of this century, some theory of chemical atoms was inevitable. And whatever theory might have been adapted, its use in investigation would have drawn it with a certainty into the essential features of the theory now established. It states the constitution of matter in terms that stand for things as they are made. The mathematician may choose the ratio of numerical notation, whether the ratio of ten or some other. But the chemist must find existing ratios of atomic and molecular mass, with such degree of exactness as he can attain. Chemical notation, the index of the atomic system, is imperfect, as science is incomplete. However defective, it is the resultant of a multitude of facts. The atomic theory has come to be more than facile language, more than lucid classification, more than working hypothesis, it is *the definition of the known truth in the existence of matter*.

The chemical atom is known, however, for what it does, rather than for what it is. It is known as a centre of action, a factor of influence, an agent of power. It is identified by its responses, and measured by its energies. Concealed as it is, each atom has given proof of its own part in the structure of a molecule. Proofs of position, not in space but in action, as related to other atoms, have been obtained by a multitude of workers with the greatest advantage. The arrangement of the atoms in space, however, is another and later question, not involved in the general studies of structure. But even this question has arisen upon its own chemical evidences, for certain bodies, so that the "configuration" of the molecule has become an object of active research.

Known for what it does, the atom is not clearly known for what it is. Chemists, at any rate, are concerned mainly with what can be made out of atoms, not with what atoms can be made of. Whatever they are, and by whatever force or motion it is that they unite with each other, we define them by their effects. Through their effects they are classified in the rank and file of the periodic system. The physicists, however, do not stop short of the philosophical study of the atom itself. As a vibratory body its movements have been under mathematical calculations; as a vortex ring its pulsations have been assumed to agree with its combining power. As an operating magnet its interaction with other like magnets has been predicated as the method of valence. There are, as I am directly assured, physicists of penetration and prudence now looking with confidence to studies of the magnetic relations of atoms to each other.[1] Moreover, another company of workers, the chemists of geometric isomerism, assume a configuration of the atoms, in accord with that of the molecule.

The stimulating truth of the atomic constitution of the molecule, a great truth in elastic touch with all science, excites numerous hypotheses, which, however profitable they may be, are to be stoutly held at a distance from the truth itself. Such are the hypotheses of molecular aggregation into crystals and other mineral forms. Such are the biological theories of molecules polymerizing into cells, and of vitality as a chemical property of the molecule. Such are the questions of the nature of atoms, and the genesis of the elements as they are now known, questions on the border of metaphysics. Let all these be held distinct from the primary law of the atomic constitution of simple molecules in gaseous bodies, an essential principle in an exact science. The chemist should have the comfortable assurance, every day, as he plies his balance of precision, that the atom-made molecules are there, in their several ratios of quantity, however many unsettled questions may lie around about them. Knowledge of molecular structure makes chemistry a science, nourishing to the reason, giving dominion over matter, for beneficence to life.

Every chemical pursuit receives strength from every advance in the knowledge of the molecule. And to this knowledge, none the less, every chemical pursuit contributes. The analysis of a mineral, whether done for economic ends or not, may furnish a distinct contribution toward atomic valence. The further examination of steel in the cables of a suspension bridge is liable to lead to unexpected evidence upon polymeric unions. Rothamsted farm, where ten years is not a long time for the holding of an experiment, yields to us a classic history of the behaviour of nitrogen, a history from which we correct our theories. The analysis of butter for its substitutes has done something to set us right upon the structure of the glycerides. Clinical inspection of the functions of the living body fain finds a record of molecular transformations too difficult for the laboratory. The efforts of pharmaceutical manufacture stimulate new orders of chemical combination. The revision of the pharmacopœa every ten years points out a humiliating number of scattered errors in the published constants on which science depends. The duty of the engineer, in his scrutiny of the quality of lubricating oils, brings a more critical inquiry into the laws of molecular movement. There is not time to mention the many professions and pursuits of *men who contribute toward the principles of chemistry* and hold a share therein. If it be the part of pure science to find the law of action in nature, it is the part of applied science both to contribute facts and to put theory to the larger proof. In the words of one who has placed industry in the greatest of its debts to philosophic research, W. H. Perkin, "There is no chasm between pure and applied science, they do not even stand side by side, but are linked together." So in all branches of chemistry, whether it be termed applied or not, the best workers are most strongly bound as one, in their dependence upon what is the known of the structure of the molecule.

Studies of structure were never before so inviting. In this direction and in that especial opportunities appear. Moreover the actual worker here and there breaks into unexpected paths of promise. Certainly the sugar group is presenting to the chemist an open way from simple alcohols on through to the cell substances of the vegetable world. And nothing anywhere could be more suggestive than the extremely simple unions of nitrogen lately discovered. They are likely to elucidate linkings of this element in great classes of carbon compounds, all significant in general chemistry. Then certain comparative studies have new attractions. As halogens have been upon trial side by side with each other, so for instance silicon must be put through its paces with carbon, and phosphorus with nitrogen. Presently, also, the limits of molecular mass, in polymers and in unions with water, are to be nearer approached from the chemical side, as well as from the side of physics, in that attractive but perplexing border ground between affinity and the states of aggregation.

Such is the extent and such the diversity of chemical labour at present that every man must put limits to the range of his study. The members of a society or section of chemistry, coming together to hear each other's researches, are better able, for the most part, to listen for instruction than for criticism. Still less prepared for hasty judgment are those who do not come together in societies at all. Even men of eminent learning must omit large parts of the subject, if it be permitted to speak of chemistry as a single subject. These considerations admonish us to be liberal. When metallurgical chemistry cultivates scepticism as to the work upon atomic closed chains, it is a culture not the most liberal. When a devotee of organic synthesis puts a low value upon analytic work, he takes a very narrow view of chemical studies. When the chemist who is in educational service disparages investigations done in industrial service, he exercises a pitiful brevity of wisdom.

The pride of pure science is justified in this, that its truth is for the nurture of man. And the ambition of industrial art is honoured in this, its skill gives strength to man. It is the obligation of science to bring the resources of the earth, its vegetation and its animal life, into the full service of man, making the knowledge of creation a rich portion of his inheritance, in mind and estate, in reason and in conduct, for life present and life to come. To know creation is to be taught of God.

---

[1] "The results of molecular physics point unmistakably to the atom as a magnet, in its chemical activities."—A. E. Dolbear, in a personal communication.

I have spoken of the century of beginning chemical labour, and have referred to the divisions and specialities of chemical study. What can I say of the means of uniting the earlier and later years of the past, as well as the separated pursuits of the present, in one mobile working force? Societies of science are among these means, and it becomes us to magnify their office. For them, however, all that we can do is worth more than all we can say. And there are other means, even more effective than associations. Most necessary of all the means of unification in science is the use of its literature.

It is by published communication that the worker is enabled to begin, not where the first investigation began, but where the last one left off. The enthusiast who lacks the patience to consult books, presuming to start anew all by himself in science, has need to get on faster than Antoine L. Lavoisier did when he began, an associate of the French Academy in 1768. He of immortal memory, after fifteen eventful years of momentous labour, reached only such a combustion of hydrogen as makes a very simple class experiment at present. But however early in chemical discovery, Lavoisier availed himself of contemporaries. They found oxygen, he learned oxidation: one great man was not enough, in 1774, both to reveal this element and show what part it takes in the formation of matter. The honour of Lavoisier is by no means the less that he used the results of others, it might have been the more had he given their results a more explicit mention. Men of the largest original power make the most of the results of other men. Discoverers do not neglect previous achievement, however it may appear in biography. The masters of science are under the limitations of their age. Had Joseph Priestley lived in the seventeenth century he had not discovered oxygen. Had August Kekulé worked in the period of Berzelius, some other man would have set forth the closed chain of carbon combination, and Kekulé, we may be sure, would have done something else to clarify chemistry. Such being the limitations of the masters, what contributions can be expected in this age from a worker who is without the literature of his subject?

In many a town some solitary thinker is toiling intensely over some self-imposed problem, devoting to it such sincerity and strength as should be of real service, while still he obtains no recognition. Working without books, unaware of memoirs on the theme he loves, he tries the task of many with the strength of one. Such as he sometimes send communications to this Association. An earnest worker, his utter isolation is quite enough to convert him into a crank. To every solitary investigator I should desire to say, get to a library of your subject, learn how to use its literature, and possess yourself of what there is on the theme of your choice, or else determine to give it up altogether. You may get on very well without college laboratories, you can survive it if unable to reach the meetings of men of learning, you can do without the counsel of an authority, but you can hardly be a contributor in science except you gain the use of its literature.

First in importance to the investigator are the original memoirs of previous investigators. The chemical determinations of the century have been imported by their authors in the periodicals. The serials of the years, the continuous living repositories of all chemistry, at once the oldest and the latest of its publications, these must be accessible to the worker who would add to this science. A library for research is voluminous, and portions of it are said to be scarce, nevertheless it ought to be largely supplied. The laboratory itself is not more important than the library of science. In the public libraries of our cities, in all colleges now being established, the original literature of science ought to be planted. It is a wholesome literature, at once a stimulant and a corrective of that impulse to discovery that is frequent among the people of this country. That a good deal of it is in foreign languages is hardly a disadvantage; there ought to be some exercise for the modern tongues that even the public high schools are teaching. That the sets of standard journals are getting out of print is a somewhat infirm objection. They have no right to be out of print in these days when they give us twenty pages of blanket newspaper at breakfast, and offer us Scott's novels in full for less than the cost of a day's entertainment. As for the limited editions of the old sets, until reproduced by new types, they may be multiplied through photographic methods. When there is a due demand for the original literature of chemistry, a demand in accord with the prospective need for its use, the supply will come, let us believe, more nearly within the means of those who require it than it now does.

What I have said of the literature of one science can be said, in the main, of the literature of the other sciences. And other things ought to be said, of what is wanted to make the literature of science more accessible to consulting readers. *A great deal of indexing is wanted.* Systematic bibliography, both of previous and of current literature, would add a third to the productive power of a large number of workers. It would promote common acquaintance with the original communications of research, and a general demand for the serial sets. Topical bibliographies are of great service. In this regard I desire to ask attention to the annual reports of the committee on Indexing Chemical Literature, in this association for nine years past, as well as to recent systematic undertakings in geology, and like movements in zoology and other sciences. Also to the Index Medicus, as a continuous bibliography of current professional literature.

Societies and institutions of science may well act as patrons to the bibliography of research, the importance of which has been recognized by the fathers of this Association. In 1855, Joseph Henry, then a past president of this body, memorialized the British Association for cooperation in bibliography, offering that aid of the Smithsonian Institution which has so often been afforded to publications of special service. The British Association appointed a committee, who reported in 1857, after which the undertaking was proposed to the Royal Society. The Royal Society made an appeal to her Majesty's Government, and obtained the necessary stipend. Such was the inception of the Royal Society Catalogue of scientific papers of this century, in eight quarto volumes, as issued in 1867 and 1877. Seriously curtailed from the generous plan of the committee who proposed it, limited to the single feature of an index of authors, it is nevertheless of great help in literary search. Before any list of papers, however, we must place a list of the serials that contain them, as registered by an active member of this Association, an instance of industry and critical judgment. I refer to the well-known catalogue of scientific and technical periodicals, of about five thousand numbers, in publication from 1665 to 1882, together with the catalogue of chemical periodicals by the same author.[1]

Allied to the much needed service in bibliography, is the service in compilation of the Constants of Nature. In the preface of his dictionary of solubilities, in 1856, Prof. Storer said "that chemical science itself might gain many advantages if all known facts regarding solubility were gathered from their widely-scattered original sources into one special comprehensive work." That the time of the philosophical study of solution was near at hand has been verified by recent extended monographs on this subject. In like manner Thomas Carnelley in England, and early and repeatedly our own Prof. Clarke in the United States,[2] bringing multitudes of scattered results into co-ordination, have augmented the powers of chemical service.

What bibliography does for research, the Handwörterbuch does for education, and for technology. It makes science wieldy to the student, the teacher, and the artisan. The chief dictionaries of science, those of encyclopædic scope, ought to be provided generally in public libraries, as well as in the libraries of all high schools.[3] The science classes in preparatory schools should make an acquaintance with scientific literature in this form. If scholars be assigned exercises which compel reference reading, they will gain a beginning of that accomplishment too often neglected, even in college, how to use books.

---

[1] "Bolton's Catalogue of Scientific and Technical Periodicals" (1885: Smithsonian) omits the serials of the Societies, as these are the subject of Scudder's "Catalogue of Scientific Serials" (1879: Harvard Univ.). On the contrary, Bolton's "Catalogue of Chemical Periodicals" (1885: N. Y. Acad. Sci.) includes the publications of Societies as well as other serials, Chemical technology is also represented in the last-named work.

[2] The service of compilation of this character is again indicated by this extract from Clarke's introduction to the first edition of his "Constants" (1873): "While engaged upon the study of some interesting points in theoretical chemistry, the compiler of the following tables had occasion to make frequent reference to the then existing lists of specific gravities. None of these, however, were complete enough. . . ."

[3] The statistics of school libraries in the United States are very meagre, the expenditures for them being included with that for apparatus. For libraries and apparatus of all common schools, both primary and secondary, the annual expenditure is set at 987,048 dollars, which is about seven-tenths of one per cent. of the total expenditure for these schools.

The library is a necessity of the laboratory. Indeed, there is much in common between what is called the laboratory method, and what might be called the library method, in college training. The educational laboratory was instituted by chemistry, first taking form under Liebig at Giessen only about fifty years ago. Experimental study has been adopted in one subject after another, until, now, the "laboratory method" is advocated in language and literature, in philosophy and law. It is to be hoped that chemistry will not fall behind in the later applications of "the new education" in which she took so early a part.

The advancement of chemical science is not confined to discovery, nor to education, nor to economic use. All of those interests it should embrace. To disparage one of them is injurious to the others. Indeed, they ought to have equal support. It would be idle to inquire into their respective advantages. This much, however, is evident enough, chemical work is extensive, and there is immediate want of it.

Various other branches of science are held back by the delay of chemistry. Many of the material resources of the world wait upon its progress. In the century just before us the demands upon the chemist are to be much greater than they have been. All the interests of life are calling for better chemical information. Men are wanting the truth. The biologist on the one hand, and the geologist on the other, are shaming us with interrogatories that ought to be answered. Philosophy lingers for the results of molecular inquiry. Moreover the people are asking direct questions about the food they are to eat, or not to eat, asking more in a day than the analyst is able to answer in a month. The nutritive sources of bodily power are not safe, in the midst of the reckless activity of commerce, unless a chemical safeguard be kept, a guard who must the better prepare himself for his duty.

Now if the people at large can but gain a more true estimation of the bearing of chemical knowledge, and of the extent of the chemical undertaking, they will more liberally supply the sinews of thorough-going toil. It must be more widely understood that achievements of science, such as have already multiplied the hands of industry, do not come by chances of invention, nor by surprises of genius. It must be learned of these things that they come by breadth of study, by patience in experiment, and by the slow accumulations of numberless workers. And it must be made to appear that the downright labour of science actually depends upon means of daily subsistence. It must be brought home to men of affairs, that laboratories of seclusion with delicate apparatus, that libraries, such has bring all workers together in effect, that these really cost something in the same dollars by which the products of industrial science are measured. Statistics of chemical industry are often used to give point to the claims of science. For instance, it can be said that this country, not making enough chemical wood pulp, has paid over a million dollars a year for its importation. That Great Britain pays twelve million dollars a year for artificial fertilizers, from without. That coal tar is no longer counted a bye-product having risen in its value to a par with coal gas. But these instances, as striking as numerous others, still tend to divert attention from the more general service of chemistry as it should be known in all the economies of civilization.

It is not for me to say what supplies are wanted for the work of chemists. These wants are stated, in quite definite terms, by a sufficient number of those who can speak for themselves. But if my voice could reach those who hold the supplies, I would plead a most considerate hearing of all chemical requisitions, and that a strong and generous policy may in all cases prevail in their behalf.

If any event of the year is able to compel the attention of the world to the interests of research, it must be the notable close of that life of fifty years of enlarged chemical labour, announced from Berlin a few months ago. When thirty years of age, August Wilhelm von Hofmann, a native of Giessen and a pupil of Liebig, was called to work in London. Taking hold of the organic derivatives of ammonia, and presently adopting the new discoveries of Wurtz, he began those masterly contributions that appear to have been so many distinct steps toward a chemistry of nitrogen, such as industry and agriculture and medicine have thriven upon. In 1850 he opened a memoir in the philosophical transactions with these words, "the light now begins to dawn upon the chaos of collected facts." Since that time the coal tar industry has risen and matured, medicine has learned to measure the treatment of disease, and agriculture to estimate the fertility of the earth. It seems impossible that so late as March of the present year, he was still sending his papers to the journals. If we could say something of what he has done we could say nothing of what he has caused others to do. And yet, let it be heard in these United States, without such a generous policy of expenditure for science as gave to Dr. Hofmann his training in Giessen, or brought him to London in 1848, or built for him laboratories in Bonn and Berlin, without such *provision by the State*, the fruits of his service would have been lost to the world. Ay, and for want of a like broad and prudent provision for research with higher education, in this country, other men of great love for science and great power of investigation every year fail of their rightful career for the service of mankind.

For the prosecution of research, in the larger questions now before us, no training within the limitations of human life can be too broad or too deep. No provision of revenue, so far as of real use to science, can be too liberal. The truest investigation is the most prudent expenditure that can be made.

In respect to the support that is wanted for work in science, I have reason for speaking with confidence. If I go beyond the subject with which I began I do not go beyond the warrant of the Association. This body has lately defined what its members may say, by creating a committee to receive endowments for the support of research.

There are men and women who have been so far rewarded, that great means of progress are in their hands, to be vigorously held for the best advantage. Strength is required to use large means, as well as to accumulate them. It is inevitable to wealth, that it shall be put to some sort of use, for without investment it dies. By scattered investment wealth loses personal force. The American Association, in the conservative interests of learning, proposes certain effective investments in science. If it be not given to every plodding worker to be a promoter of discovery, such at all events is the privilege of wealth, under the authority of this association. If it be not the good fortune of every investigator to reach knowledge that is new, there are, every year, in every section of this body, workers of whom it is clear that they would reach some discovery of merit, if only the means of work could be granted them. Whosoever supplies the means fairly deserves and will receive a share in the results. It is quite with justice that the name of Elizabeth Thompson, the first of the patrons, has been associated with some twenty-one modest determinations of merit recognized by this association.

"To procure for the labours of scientific men increased facilities" is one of the constitutional objects of this body. It is time for effectiveness towards this object. The Association has established its character for sound judgment, for good working organization, and for representave public interest. It has earned its responsibility as *the American trustee of undertakings in science.*

"To give a stronger . . . impulse . . . to scientific research" is another declaration of what we ought to do. To this end larger endowments are necessary. And it will be strange if some clear-seeing man or woman does not put ten thousand dollars, or some multiple of it, into the charge of this body for some searching experimental inquiry now waiting for the material aid. The committee upon endowment is ready for consultation upon all required details.

"To give . . . more systematic direction to scientific research" is likewise stated as one of our objects. To this intent the organization of sections affords opportunities not surpassed. The discussions upon scientific papers give rise to a concord of competent opinions as to the direction of immediate work. And arrangements providing in advance for the discussion of vital questions, as formally moved at the last meeting, will in one way or another point out to suitable persons such lines of labour as will indeed give systematic direction to research.

In conclusion, I may mention another, the most happy of the duties of the American Association. It is to give the hand of hospitable fellowship to the several societies who year by year gather with us upon the same ground. Comrades in labour and in refreshment, their efforts reinforce us, their faces brighten our way. May they join us more and more in the companionship that sweetens the severity of art. A meeting of good workers is a remembrance of pleasure, giving its zest to the aims of the year.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

1851 EXHIBITION SCIENCE SCHOLARSHIPS.—Her Majesty's Commissioners for the Exhibition of 1851, assisted by a committee of gentlemen experienced in scientific education, have made the following appointments to the science scholarships for the year 1892. The scholars have been students of science for at least three years, and have been recommended for the scholarships by the authorities of their respective Universities or Colleges, as indicating high promise of capacity for advancing science, or its applications, by original research. The scholarships are of the value of £150 a year, and are tenable for two years (subject to a satisfactory report at the end of the first year) in any University at home or abroad, or in some other institution to be approved of by the Commissioners. The scholars are to devote themselves exclusively to study and research in some branch of science, the extension of which is important to the industries of this country.

ARTHUR ELLIS, Major-General,
Secretary.

18, Victoria-street, Westminster, August, 1892.

University of Edinburgh.—Mr. Andrew John Herbertson.
,, Glasgow.—Mr. James Blacklock Henderson.
,, Aberdeen.—Mr. John Macdonald.
Mason Science College, Birmingham.—Mr. Lionel Simeon Marks.
University College, Bristol.—Mr. George Lester Thomas.
Yorkshire College, Leeds.—Mr. Harold Hart Mann.
University College, Liverpool.—Mr. James Terence Conroy.
Owens College, Manchester.—Mr. Thornton Charles Lamb.
University College, Nottingham.—Mr. Edward Arnold Medley.
Firth College, Sheffield.—Mr. William Henry Oates.
University College of North Wales.—Mr. Edward Taylor Jones (*conditionally*).
Queen's College, Cork.—Mr. George Ryce.
,, ,, Galway.—Mr. William Gannon.
University of Toronto.—Mr. Frederick J. Smale.
,, Adelaide.—Mr. James Bernard Allen.
,, New Zealand.—Mr. David Hamilton Jackson.
,, Sydney (*postponed from* 1891).—Mr. Samuel Henry Barraclough.

ROYAL COLLEGE OF SCIENCE, LONDON (SESSION 1891–92).—List of Scholarships, Prizes, and Associateships, awarded July 1892:—

First Year's Scholarships... ...	Spencer, Bernard E. West, George S. Gray, Charles J. Verney, Harry.	
Second Year's Scholarships ...	Allan, William. Melton, George R.	
"Edward Forbes" Medal and Prize of Books for Biology	West, William Vanstone, John H.	2 Medals and Prize divided.
"Murchison" Medal and Prize of Books for Geology	Starling, Sydney E.	
"Tyndall" Prize of Books for Physics Course I	Spencer, Bernard E.	
"De la Beche" Medal for Mining ...	Cooke, Lewis H.	
"Bessemer" Medal and Prize of Books for Metallurgy	Jeans, Harold.	
"Frank Hatton" Prize of Books for Chemistry	Perry, George H.	

Prizes of Books given by the Department of Science and Art.

Mechanics	Longbottom, John G.
Astronomical Physics	Bruce, James.
Practical Chemistry	Perry, George H.
Mining	Cooke, Lewis H.
Principles of Agriculture ...	Jones, Thomas.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, August 16.—M. Duchartre in the chair.—Theory of a condenser introduced into the secondary circuit of a transformer, by M. Désiré Korda.—Vaporization in boilers, by M. de Swarte.—On some new combinations of piperidine, by M. Raoul Varet.—On an application of chemical analysis for fixing the age of prehistoric human remains, by M. Adolphe Carnot. This determination is based upon the progressive diminution of fluorine contained in the fossil bones of the various geological ages. If the quantity contained in the most ancient remains be designated by 1, we shall have 0·64 for Tertiary remains, 0·35 for "Quaternary," and 0·05 or 0·06 for the recent ones. This fact was utilized in fixing the age of a human tibia found in the sandy layers of Billancourt (Seine) in the neighbourhood of some remains of undoubted Quaternary origin. The ratio of the quantity of fluorine contained in the animal fragments to that in the human tibia was found to be 0·469 or 0·578 to 0·066. This establishes the more recent origin of the tibia.—On a new genus of permio-carboniferous stems, the *G. Retinodendron Rigolloti*, by M. B. Renault. The specimen upon which this new genus has been founded was discovered by M. Rigollot in the silicified layers of Autun. It represents a stem 12 mm. thick, 3 mm. of which belong to the wood and 9 mm. to the bark. The latter is composed of several eccentric zones of gum or resin canals, and of cells with sclerified walls in regular alternation. The canals are arranged in continuous circular lines; their cavities enclose a brown substance which is sometimes granular. The structure of the wood indicates that the new genus belongs to the gymnosperms; its density and the small thickness of the ligneous cellular rays distinguish it from the ordinary cycads, while their composite nature makes it impossible to class them with the conifers. Hence it belonged to a family of gymnosperms which is actually extinct. It may be concluded that at no other epoch have the plants secreting gums, resins, tannin, &c., been more abundant, and that the carbonization of these products is the origin of the yellow or brown substances found not only in the bituminous schists, forming bands or small lenticular patches, but also in pitcoal, impregnating more or less the preserved tissues, and in cannel-coal, enclosing a large number of recognizable vegetable fragments.—Pancreatic diabetes, by MM. Lancereaux and A. Thiroloix. Further experiments show that there exists a diabetes actually consequent upon the destruction of the pancreas; this diabetes is not, however, caused by the absence of the external glandular secretion, but simply by the absence of the liquid secreted internally by the gland and absorbed by the blood-vessels and the lymphatics.—On a new treatment of the glanders, by MM. Claudius Nourri and C. Michel. This is identical with that applied recently to human tuberculosis, with which it has much in common.

THURSDAY, SEPTEMBER 1, 1892.

EPIDEMICS, PLAGUES, AND FEVERS.

Epidemics, Plagues and Fevers: their Causes and Prevention. By the Hon. Rollo Russell. (London: Edward Stanford, 1892.)

IN this handbook the author has aimed at collecting together the main facts concerning preventable diseases and presenting them in a convenient form for the use of those interested in the promotion of public health. The work is in the main a compilation of extracts from the most varied sources, and references are given which enable the original authorities to be consulted. It is difficult to speak too highly of the care and industry with which Mr. Russell has fulfilled this task, and of the completeness with which the work has been brought up to date.

In an introductory chapter on the nature of spreading diseases in plants and animals the analogy is traced between such processes as dry-rot and yeast fermentation, and the action of disease germs upon the animal organism; a short account is given also of various epizoötic diseases.

Passing to the main subject of the book, the author deals *seriatim* with the different human diseases of microparasitic origin. A long chapter is devoted to cholera. Accepting provisionally Koch's comma-bacillus as its cause, Mr. Russell exhibits in a mass of evidence the conditions of filth and water pollution which enable the disease to maintain itself in its native home, India, and to spread thence in epidemic visitations to other parts of the world. In many parts of India much has been done by sanitary measures, such as drainage and improved water supply, to reduce the incidence of cholera: in a later part of the book stress is justly laid on the responsibility which rests on England in the matter of the sanitation of India. The measures by which cholera may be arrested are set forth in full, the most important being personal cleanliness, a pure water supply, and the disinfection of dejecta and soiled linen. No adequate account is given of the measures of notification and supervision which in this country replace strict quarantine.

Another important section of the book is devoted to consumption, which it is a pleasure to find included amongst preventable diseases. Nothing is more lamentable than the carelessness with which a phthisical patient is allowed to spread infection broadcast by the sputum, and though public opinion is not yet ripe for the question of seclusion of cases of consumption, much might yet be done by educating patients to disinfect the sputum and use reasonable precautions against the infection of members of their families. The diffusion of tubercle by means of domestic animals and especially by milk is enforced by Mr. Russell, and attention is drawn to the general sanitary measures such as drainage and ventilation which have already reduced its mortality in this country.

In the chapter on diphtheria mention is made of the recent researches of Klein and others showing the connection of this disease with a certain disease in cows and in cats. The author has drawn also on Dr. Thorne Thorne's recent Milroy lectures, but he has hardly laid sufficient emphasis on the aggregation of children in schools as the main cause of the late increase of urban, as compared with rural diphtheria mortality, a point to which Dr. Thorne draws especial attention.

The section on influenza is based on the most recent observations, and even contains in a note some account of Pfeiffer's and Canon's influenza bacillus. Exception must be taken to the statement that this organism is present in immense numbers in the blood. In the sputum it is extremely abundant, but in the blood, as a rule, only in the scantiest numbers.

Scarlet fever and small-pox have each a comparatively short chapter devoted to them. That on scarlet fever contains mention of the so-called "Hendon disease" in cows, to which the extensive outbreak in the north-west of London in 1885 was traced, and a good practical epitome of the precautions to be observed in the sick room. In the section on small-pox vaccination statistics are given, but we find no reference to the elaborate Local Government Report by Dr. Barry on the late Sheffield epidemic, which contains a mine of information on the most serious outbreak of small-pox in England in recent years, and should certainly have been noticed. The spread of the disease by aërial diffusion from small-pox hospitals is clearly illustrated.

Typhoid fever receives long and thorough consideration. Mr. Russell accepts the "typhoid bacillus" of Eberth, Klebs, and Gaffky as the true virus of the disease—a conclusion which is far from settled in the minds of many, inasmuch as the true lesions of the disease have not been reproduced by it. But this does not affect the questions at issue. The ordinary method by which the disease spreads, viz., excremental pollution of drinking water, is abundantly illustrated by numerous examples, and the contamination of milk is likewise mentioned. The thorough disinfection of typhoid dejecta is clearly a matter of the first importance, and a sound practical method of accomplishing this is much to be desired; at present it must be admitted that no adequate means has been devised.

Amongst the numerous other diseases which Mr. Russell has treated of, we are glad to notice that pneumonia finds a place; it is undoubted that some forms at least of inflammation of the lungs are infectious and preventable in the same manner as other specific fevers. The claims of rheumatic fever, which has also been included, to a similar position, are to say the least doubtful.

In the concluding chapters of the book, Mr. Russell deals with more general problems, such as susceptibility, immunity, the distribution of microbes, the origins of epidemics, and so forth. Gathering his evidence from various sources, he deals with these matters in a very impartial way. Thus in discussing immunity, while accepting provisionally the doctrine of phagocytosis, he by no means regards it as the only means by which micro-organisms are eliminated from the body. The germicidal powers of the fluids of the body receive due consideration as at least an equally important defensive agency. The scheme of a National Health Service is discussed in an appendix.

Mr. Russell is to be congratulated on the service which he has done to Public Health by the collection of this mass of information on its more important topics. It is only natural that a work which is essentially a compilation, should be of a somewhat patchwork character; but it is to be regretted that in some of the sections the different paragraphs do not offer more coherent reading. It would further have been an advantage to the general public, whose education in these matters is so essential an element in the further progress of public health, if so many technical terms had not been used without explanation. Occasional looseness of expression is to be noticed. As when we read of "Bacterium termo, the microbe of impure water," or, "the Zeiss system magnifies three to four thousand times." But to those for whom the book is specially written, those interested or officially concerned in the promotion of health, it will prove a valuable work of reference.

THE PHYSIOLOGY OF THE INVERTEBRATA.

The Physiology of the Invertebrata. By A. B. Griffiths, Ph.D., F.R.S. (Edin.), F.C.S. (London: L. Reeve and Co., 1892.)

STUDENTS of biology, and especially of physiology, have long wanted a book treating of the physiological problems of the invertebrate animals. It is true that what is sometimes called human physiology is in great measure the physiology of the lower animals. Physiologists, however, generally select for experiment animals which are as much as possible like themselves; it is comparatively seldom that they invade the invertebrate branches of animal life. There are vast fields there for exploration which are almost untouched from the physiological standpoint, and one can hardly doubt that great treasures in the way of fact and reasoning could be unearthed, which would throw light on the functions not only of these lower creatures themselves, but on the life problems of the higher animals also. The present book by Dr. Griffiths will therefore be welcomed as a first attempt to fill this gap. He is well known as one of the few who have carried the method of physiology down to the invertebrates, and his researches have been marked by great industry and patience.

In treating of invertebrate physiology, it is obvious that there are two courses open to a descriptive writer: one is to take the various sub-kingdoms as the main headings, and to treat of the different functions of each before proceeding to the next; the other method is to head the chapters with the functions—circulation, respiration, and the like—and to describe each of these in the various branches of the invertebrata. No doubt there is much to be said for each course. The latter, which is the one adopted in the present volume, appears, however, to have these disadvantages, that it involves a good deal of repetition, and that each chapter is split up into a number of small paragraphs, and there is thus but little continuous narrative. This is increased by the habit the author has of making extensive quotations, so that there is little uniformity of style; half a page will be given in the flowing style of Huxley, and the next half in the less fluent English of other writers. It appears to us it would have been better if Dr. Griffiths had given the results of other investigators in his own language. This, however, is a minor point. Passing to more important matters, we may proceed to enquire if the book really meets the want which has been stated to exist; and the answer to such an enquiry must depend on whether the good in it outweighs the bad, or the reverse. The features in the book which appear to be excellent, are, first, the evidence that a vast amount of pains has been expended in its compilation; and on those subjects to which the author has devoted research-work—the excretions, the blood gases and salts, and digestion—he is distinctly good, and men of science will be glad to have all Dr. Griffiths' experimental work in a handy form, instead of having to hunt it out from journals. Then the whole is exceedingly interesting, and will no doubt stimulate others to prosecute new work on the subject.

There is, however, much that must come in for adverse criticism, and the first point to which attention may be called is not so much the fault as the misfortune of the author in having to deal with a portion of biological science which is in an embryonic condition. Where little is known little can be said, and some of the chapters are little more than anatomy, with physiological excerpts from anatomical works. Again, on certain subjects such as muscular contraction and blood coagulation, the author is evidently not acquainted with the literature of his subject, and in other cases again there is internal evidence to show that Dr. Griffiths has not consulted original memoirs, but abstracts of them that have appeared elsewhere.

The main objection, however, that physiologists will feel about the work, is the conclusion to which they can hardly help coming, that Dr. Griffiths has not the advantage of being a physiologist; there is no wide grasp of the facts and hypotheses with which he has to deal, and the hand of the amateur is continually to be seen. Take as an instance the following sentences: "Urea is a product of *more or less* complete oxidation of *organic substances*, and is *formed in muscular tissues* by the *disintegration of the anatomical elements.* Uric acid on the other hand is the result of an incomplete oxidation, and is produced for the most part *in the blood*, or its equivalent when such fluid is *surcharged with peptones* which the tissues are unable to assimilate." (The italics are our own.) Again, in the chapter on the physiology of the sense organs, the difference between the tactile sense and general sensibility has not been apparently grasped; and even on subjects which the author has himself investigated, very often elementary facts have escaped him. Thus it appears that uric acid is the most constant of the nitrogenous metabolites in the invertebrata, but we are not in the majority of instances told how this insoluble substance is held in solution in an aqueous liquid. We also read that after starch has been digested with the secretion of the hepato-pancreas, it gives a precipitate of cuprous oxide with Trommer's test, and this is regarded as sufficient evidence of the formation of glucose. No reference is made to the fact that anylolytic ferments in the vertebrata produce maltose and not glucose from starch. Again, one would judge from Dr. Griffiths' words, that he regards the formation of leucine and tyrosine as the chief functions of a proteolytic ferment, or from the omission of hæmocyanin from the chapter on respiration that it was not a respiratory pigment, though this would be corrected by reference to the chapter on the blood.

Taking a general survey of the whole, we see that the book is far from perfect. Few books are when they first appear, and much that is faulty can be corrected in subsequent editions. We must, however, congratulate Dr. Griffiths on being the first to break new ground by producing a work on the subject, as well as on the good points that the book exhibits, and to which allusion has already been made.

W. D. H.

THE DESIGN OF RETAINING WALLS AND RESERVOIR DAMS.

A Text-Book on Retaining Walls and Masonry Dams. By Prof. Mansfield Merriman. (New York: John Wiley and Sons, 1892.)

BEFORE entering upon the investigation of retaining walls and their design, the author devotes two chapters to the consideration of earthwork slopes and the lateral pressure of earth. Owing to the changeable condition of earth under the influence of moisture, and the variable nature of any stratum, it is impossible to obtain strictly exact expressions for the forms of slopes of cuttings and embankments, or definitely accurate values for the lateral pressure of earth; but, nevertheless, the formulæ deduced by the author from general principles are useful in serving as a guide to correctness of design. It is indicated that theoretically an earthwork slope should be curved, becoming flatter towards the base; and though a straight slope is always adopted for cuttings and embankments, the curved form left by slips is somewhat in accord with this theory. The inclination of slopes must indeed depend on the nature of the soil, and must be flatter in made ground than in cuttings; whilst efficient drainage and protection of the surface of the slopes from the weather are equally important for ensuring stability.

The pressure of earth is the basis of all theoretical principles relating to retaining walls, and it has formed the subject of numerous experimental investigations in England and on the Continent which might have been advantageously referred to in this book. The author adopts the view that the pressure is normal to the back of the wall; but as this theory is not universally accepted, he has also obtained a formula for inclined pressure. A retaining wall may fail by sliding or rotation, and the masonry is assumed to be laid dry, owing to the uncertain amount of cohesion in mortar joints. In practice, however, retaining walls of any height are built with cement mortar; and sliding occurs at the base, or even sometimes on detached slippery surfaces of clay below the base; whilst rotation is due to excessive pressure on yielding foundations at the front of the wall. Stability largely depends upon the nature of the foundation and the backing behind the wall. A clay foundation is far less trustworthy than gravel, and sliding is most effectually prevented in slippery soils by carrying down the foundations well below the surface; whilst careless backing up with bad materials, not brought up in their layers, may push over the wall. Efficient drainage, moreover, at the back of the wall, and outlets for water at intervals through the wall to prevent its accumulation behind, are almost as important considerations as the design of the wall. A wall leaning over backwards is shown to be the most economical; but though this form might be adopted for building against an embankment, it would not be convenient for a wall built in a timbered trench to retain the side of a cutting. The four chapters relating to earthwork and retaining walls, which comprise the main portion of the book, will be very useful for practical engineers who desire to extend their theoretical knowledge on these subjects; but students should bear in mind that an almost exclusive treatment of the theoretical aspect of these questions must be supplemented in actual design by practical experience.

The theory of the strains on masonry dams, considered in the concluding chapter, is more precise, owing to the exactness of our knowledge of the laws of water pressure as compared with the uncertain and variable pressure of earth. The well-known condition of stability, that the lines of resultant pressures, with the reservoir empty and full, should fall within the middle third of the cross section, is explained, as well as the uncertainty which exists as to the actual distribution of the pressures throughout the dam. The lines of resultant pressures for any given section are easily obtained graphically, for the line of pressure with the reservoir empty is the locus of the centres of gravity of the sections above a series of base lines taken down the dam, and the actual pressure is the weight of these successive sections; whilst the line of pressure with the reservoir full is the modification produced in the former line by the addition of the water pressure at the successive depths. The theoretical section given on page 110 resembles the section of the Furens dam in France, the highest masonry dam hitherto erected, the form of which was determined by elaborate analytical calculations. The principles laid down concerning masonry dams require to be supplemented by two practical considerations, namely, that high masonry dams must be founded on solid rock to secure them against undermining and settlement, which would be fatal to their stability; and that their inner face should be coated with an inpervious material, to prevent the infiltration which otherwise takes place through their joints at great depths. In taking the pressure due to waves on the top three or four feet of the dam below the water as equivalent to the greatest observed pressure exerted by waves on the sea-coast, the author far exceeds the probable limit; for ocean waves, owing to the great extent of the exposure and the depth, are impelled with a much greater force than the waves of a comparatively small and sheltered reservoir. The additional strength given to a dam by arching it towards the reservoir is very properly neglected in the calculation of its stability, for besides being difficult to estimate precisely, this increase in strength is inappreciable in a long dam, and even in the short Furens dam the arched form was merely regarded as an extra safeguard.

The book is clearly and concisely written; it is illustrated by numerous diagrams in the text; and problems to be worked out are given at the end of most of the articles, each of which deals with a subject under a special heading.

OUR BOOK SHELF.

Directions for Collecting and Preserving Insects. By C. V. Riley. (Washington: Government Printing Office, 1892.)

DURING the last few years there has been in America a considerable increase of the number of persons interested in entomology. This may be due mainly to the fact that farmers have very practical reasons for studying insects, but no doubt it springs in part from a growing appreciation of the scientific aspects of the subject. However the increased interest is to be explained, one of its results is a constant demand, especially from correspondents of the U.S. Museum and the Department of Agriculture, for information as to how to collect, preserve, and mount insects. In the present work Mr. Riley undertakes to meet this demand. He also brings together a number of directions on points connected with such matters as the proper packing of insects for transmission through the mails or otherwise; labelling; methods of rearing; boxes and cabinets; and text-books. The work was prepared as a part of a Bulletin of the National Museum, but is also issued separately; and we need scarcely say that it is likely to be of great service to the class for whose benefit it was originally planned. Mr. Riley knows his subject so thoroughly that he is able to explain it simply and clearly, and the value of the text is enhanced by a large number of suitable illustrations. We may note that, in a paragraph on the scope and importance of entomology, he refers to various estimates of the number of insects in the world. Linnæus knew nearly 3000 species. In 1853 Dr. John Day thought there might be 250,000 species on the globe. Dr. Sharp's estimate thirty years later was between 500,000 and 1,000,000. In 1889 the estimate formed by Sharp and Walsingham reached nearly 2,000,000. Mr. Riley thinks even this estimate too low. Considering that species have been best worked up in the more temperate portions of the globe, that in the more tropical portions a vast number of species still remain to be characterized and named, that many portions of the globe are entomologically unexplored, and that even in the best worked-up regions by far the larger portion of the Micro-Hymenoptera and Micro-Diptera remain absolutely undescribed in our collections, and have been but very partially collected, he is of opinion that to say there are 10,000,000 species of insects in the world would be "a moderate estimate."

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Science and the State.

IN last week's NATURE I find the statement that I was allowed to leave the public service "without the slightest recognition" by the State.

However distasteful it may be to me to have anything to say on this subject, I feel bound, in justice both to Lord Salisbury's and to Mr. Gladstone's former Governments, to point out that it is incorrect. Very substantial recognition was awarded me by both; and the late Lord Iddesleigh, in offering to recommend me for a Civil List pension, expressly put it as an honour.

The distinction which the Queen has recently been pleased to confer upon me must therefore, I am afraid, be placed in the category of "unearned increments." T. H. HUXLEY.

Barmouth, Wales, August 30, 1892.

[We did not refer to such recognition as is implied in the granting of pensions. What we meant was that the State ought to have marked its appreciation of Prof. Huxley's great services by conferring on him some national distinction of the kind he has now received.—ED.]

An International Zoological Record.

ON this subject Mr. Minchin (NATURE, August 18, p. 367) writes as a Recorder, and he writes feelingly. Those who use Records can write with feeling too. The absurd waste of labour involved, even in the production of a single Record, by the present system is hardly to be excused by the consideration that the labour is voluntary. I say "voluntary" advisedly, for some three or four pounds is no pay for a month's hard work. And yet, for all this toil, the result, when, after a year or so of delay, we are presented with it, is notoriously unsatisfactory. It is indeed impossible for a single individual—often very far from acquainted with the subject he is recording—to work through all the scientific literature of the whole world for the preceding year, in search of some scattered references. Actually impossible, for the literature of one year never comes completely to hand before the end of the next, and perhaps not then; and this the Recorders seem to know, for many of them postpone their work till the autumn, though it should have already been published in the spring. The acceptance of Mr. Minchin's admirable suggestions would do away with the ridiculous decimiplication of labour, but it would neither make the Record complete nor hasten its publication. The public are probably more anxious for the latter results than they are for the relief of the Recorders.

Almost absolute completeness, a higher standard of work, and greater expedition, would probably be attained by some such organization as the following:—In each country a Bibliographer, possessing an all-round acquaintance with the subjects to be recorded; this bibliographer simply to record, on separate slips, titles and places of publication of papers issued in *his own* country (and therefore probably in his own language), and to mark by some symbol the groups of animals or facts alluded to in those papers. An Editor-in-chief, situated in some convenient postal and printing centre, *e.g.*, Naples, London, New York, Berlin, Paris, or Washington; this editor to govern the general plan of the Record, at present somewhat anarchic, to sort and distribute to specialists the slips which he receives from the bibliographers, and to edit the work. Lastly, for each group or division of a group, a Specialist, who, on receipt of the title-slips from the editor, should prepare the lists of new species, the abstracts of the papers, and a general review of advance in the subject. It may be pointed out that, by means of carbon-paper, title-slips can be easily written in duplicate or even triplicate; thus, by one writing of the bibliographer, slips can be prepared for the information of two or three specialists.

Such a scheme has the following advantages:—The literature is only gone through twice, instead of perhaps a dozen times. There is a possibility of completeness without much effort. Dates of publication can be ascertained with greater certitude. The quality of the work is improved by the employment of those specialists who will never consent to the colossal drudgery of the present system. Promptness of publication is possible. Thus, all slips for Europe and America could easily be sent to the editor within the first fortnight of the New Year, and by him transferred to specialists before the end of January. Literature from a greater distance would have to be sorted later on. Any specialist worthy of the name would already have seen most of the papers, and, with the help of abstracts from authors, could be ready with his manuscript before March, by which time the literature from the most distant parts would have come in and might be incorporated. The Record should go to press in separate divisions, so that the Birds need not be kept waiting because the Worms were not early; and the whole might well be issued in April or May.

The financial question must not be overlooked. As an International affair the sources of revenue of such a Record would be greatly increased. Not only Zoological and Royal, but also Geological Societies of all nations should be invited to contribute towards its expenses. The printer and the editor would have to be paid as now, the editor perhaps a trifle more. The postage would be a larger item, but postage is now so cheap that it really makes little difference. The bibliographers would of course have to be paid; but then the work of a bibliographer, even for the most prolific country, would be far less than the present work of the Recorder of, say, the Brachiopoda, who, I believe, gets about 30s. Some specialists would wish to be paid, but others would probably be satisfied by receiving the information from bibliographers and the abstracts and separate copies from authors. These latter, it is presumed, would gladly send single copies of their works for the use of a well-known specialist, but it is rather hard to have to distribute them to a dozen different Records, as one is requested to at present. The sale of such a work would be greater than that of the present incomplete and tardy publications. Besides, the promoters would doubtless be prepared to sell the various sections separately—an urgent reform that has long been clamoured for in vain; this alone would materially increase the receipts.

Having thought much of this subject during the last five years, and having talked it over with many Recorders and bibliographers, I venture to take this opportunity of putting forward the crude outlines of an undeveloped scheme. There is no wish to offend those unselfish toilers who have done and are doing so much for us, or the corporate bodies that support them. But this is a question that must be approached from a cosmopolitan standpoint. Men of science all the world over should support it with purse and person. All petty considerations of nationality, even of language, should be sunk. The aim of the work should be the advancement of science; only if it is truly International, can it possibly be realized out of Utopia. F. A. BATHER.

British Museum (Nat. Hist.), August 19.

PERHAPS you will kindly allow me, as the author of a certain pamphlet on "The Organization of Science," to say a few words on Mr. Minchin's letter (NATURE, August 18), which naturally had an especial interest for me. I am sorrowfully pleased to find the principles advocated in my pamphlet illustrated so well by concrete instance, and, needless to say, I heartily wish Mr. Minchin success in his endeavour to introduce order into at least one province of the scientific class, seeing that the text of my pamphlet may be exactly summed up in his remark—"A great need . . . is the intelligent *organization* of scientific research."

One point in Mr. Minchin's letter was of especial interest to me, for he invites the Royal Society to take in hand this work of organization, instead of leaving private individuals to execute at a great sacrifice the work which this wealthy corporation systematically neglects. Now a reference to my pamphlet (pp. 11-14) will show that this was a main thesis sustained there. Whether Mr. Minchin has done me the honour to read my pamphlet and is already preaching my crusade for me, or whether the similarity between our views is a simple coincidence of opinion, I know not, but whichever be the case, it is peculiarly gratifying to me to receive practically an endorsement from one whose experience renders him so especially qualified to speak with authority. A FREE LANCE.

London, August 23.

"The Limits of Animal Intelligence."

MR. DIXON has not, I think, quite grasped the main tendency of my paper read before the International Congress of Experimental Psychology. Nor is this to be wondered at. He quotes from a brief summary of what was itself but an abstract of a portion of a work on Comparative Psychology on which I am engaged. I am in agreement with nearly all that Mr. Dixon says, except where he misunderstands my position, and except in the opinion he expresses in the last sentence. When Mr. Dixon says, "Of course it is true that my knowledge of *my own* psychology does differ in kind from my knowledge of that of animals, but it differs in exactly the same way from that of all other men," he is expressing the views which I, in common with most men who have seriously studied the question, hold. And when he says, "If in no case is 'an animal activity to be interpreted as the outcome of the exercise of a higher psychical faculty if it can be fairly interpreted as the outcome of one which stands lower in the psychological scale,' the same rule should be applied to the (scientific) interpretation of human activities," I can only say that I heartily agree with him. Since, therefore, we have so much in common, I do not propose to occupy valuable space in discussing the outstanding points of difference between us. I may perhaps be allowed, however, to take advantage of the courtesy of the Editor of NATURE, and to say a few words in elucidation of the thesis I very imperfectly set forth in my paper, a thesis based entirely on observation and induction.

In the first place the study of my own mental processes, and of the nature and sequence of my own states of consciousness, has led me to the conclusion that there is a great difference between the mere feeling or awareness of certain relationships and the clear cognizing of these or other relationships. When I am bicycling, or playing tennis, or when I am living the practical life of naïve perception, I am aware of, and shape my actions in accordance with, a feeling of the relations which the objects of the external world bear to me and to each other. The greater part of my practical skill in action and of such intelligence as I show in meeting the emergencies that occur in my active life, are the outcome of this awareness of relations. But when I begin to attempt to *explain* phenomena, and to formulate my knowledge of the world, I find I am forced to pay special attention to these relationships *as such*, and to clearly and precisely cognize them. This conclusion, I repeat, is the outcome of observation, and is not, so far as I am aware, the result of any *a priori* considerations.

Looking back upon my own past, and collating the results with those reached by other observers, I find that the mere feeling or awareness of relations is prior in development to the clear and precise cognition of them. The awareness of relations seems to be, in fact, the undifferentiated germ from which their clear cognition has been developed; it is not knowledge, properly so called, but it is the raw material from which knowledge and the products of the intellect are shaped. Hence I conclude that the order of development or evolution in man is—first, the practical awareness of relations among phenomena, and then subsequently the cognition and clear knowledge (in the full sense of the word) of these relations as such.

Now, passing to the psychology of animals, such as the higher mammalia, the hypothesis suggests itself that they are still in the stage of mere awareness, and have not reached the stage of clear cognition, which, as I showed in my paper, involves reflection and introspection. This is put forward as an hypothesis; one based on observation and the doctrine of evolution; and one to be treated in the same spirit and on the same methods as other scientific hypotheses. It must be submitted to the touchstone of verification. The question is:—Are the activities of animals explicable on the supposition that the agents are merely aware of the relations; or must we suppose that they fully cognize them? I feel sure that my own practical activities are in the main based on awareness, and this leads me to suspect that the practical activities of animals are also of like psychological implication. The matter must, however, so far as is possible, be put to the test of experiment and observation. I have conducted from time to time experiments with the object of ascertaining how far there is evidence in the dog of true cognition—of causation for example. I am inclined to believe as the result of my observations that there is nothing beyond a simple awareness of the causal nexus. But I am far from wishing to dogmatize in the matter. I am chiefly concerned that the phenomena should be carefully observed, and that experiments should be conducted on definite scientific lines.

In conclusion I must be allowed to say that the phrases "difference in kind" and "difference of degree" savour somewhat of mere academic discussion, and may perhaps be left for those who deal with the matter on *a priori* lines and not from the standpoint of evolution. I for one do not for a moment question that the mental processes of man and of animals are alike products of evolution. The power of cognizing relations, reflection and introspection, appear to me to mark a new departure in evolution. But whether, as I am at present disposed to hold, the departure took place through the aid of language coincident with, or subsequent to, the human phase of evolution; or whether, as other observers and thinkers believe, it took place, or is now taking place, in the lower mammalia or in other animals, is a matter for calm, temperate, and impartial discussion founded on accurate, and, as far as possible, crucial experiment and observation. C. LLOYD MORGAN.

Rules of Nomenclature.

In your review of Mr. Massee's monograph of the Myxogastres (NATURE, p. 365) I notice the sentence, "Under the generally accepted rules of nomenclature, this leads to Massee standing as the authority for many species, transferred by him, in reality, to another genus." I take this to mean that, for example, a species of which the trivial name is, say, *abii*, and which was originally described by an author Xyz, and referred (erroneously) by him to the genus *Cdia*, has been transferred now to another (the correct, according to present knowledge) genus *Efia*, and the name is now printed in this work not as *Efia abii*, Xyz, but as *Efia abii*, Massee. I am aware that this course is frequently adopted, but surely not "under the generally accepted rules of nomenclature." There is no copy of the British Association "Rules" within reach here, but my recollection is that they prescribe a different course, viz., to retain as authority for a species the name of the original describer, and that is the course adopted in, I think, most of the *Challenger* reports, and by very many zoologists. I may state briefly as an example the first case that occurs to me—I have no systematic books here to refer to. (1) About 1870 Cunningham described a new Ascidian as *Cynthia gigantea*. (2) About 1880 Herdman transferred that species to the genus *Molgula*. (3) In the *Challenger* report this species figures as *Molgula gigantea*, Cunningham; and I would submit that that, rather than the course indicated in the review, is "under the generally accepted rules of nomenclature." W. A. HERDMAN.

Tarbert, Loch Fyne, August 23.

An Earthquake Investigation Committee.

IT may perhaps interest you and your readers to hear that by the Imperial ordinance of June 25 a committee has been established for the investigation of the earthquake phenomena, with the view of finding methods of predicting earthquakes, if possible, and of ascertaining the nature of construction, building, and otherwise, best calculated to resist the effect of the shocks. President Kato, of the Imperial University, has been nominated the president, and myself the secretary. Other members of the Committee are Furnichi (Director and Professor of Civil Engineering, Engineering College, and Head of the Engineering Bureau of the Department of the Interior), Tatonno (Professor of Architecture, Engineering College), Tanabe (Professor of Civil Engineering, Engineering College), Tanakadate (F.R.S.E., and Professor of Physics, Science College), and Nagaoka (Assistant Professor of Physics, Science College), Koto (Professor of Geology, Science College), and Kochibe (of the Geological Survey), Sekiya and Omori (Seismologists), Nakamura (of the Meteorological Bureau), and a foreign member, Prof. J. Milne Other members will be nominated by and by. The Parliament has granted 42,000 yen for this year, chiefly for the purchase of various instruments. The committee will be glad to receive any communication or suggestion on the subject. Address: Earthquake Investigation Committee, care of the Department of Education, Japan. D. KIKUCHI.

Imperial University, Tokyo, July 21.

Prehistoric Epochs.

I DO not think that the English authors who have written on prehistoric times have divided the Pleistocene in *epochs*, as Prof. G. de Mortillet has done in France. Would it be possible to use in England subdivisions similar, or almost similar, to those used in France, and almost generally adopted, although that classification is often subject to criticism?

According to Prof. G. de Mortillet, Palæolithic silex have been found in England that could be respectively related (1) to the type of Chelles or *Chelléen* (Hoxne, Biddenham); (2) to the type of the Moustier or *Mousterien* (Creswell, High Lodge); (3) to the type of Solutré or *Solutréen* (Creswell); (4) and to the type of La Madeleine or *Magdalénien* (Creswell, Kent's Hole). The same author says that at Creswell (Derbyshire) Palæolithic silex belonging to the *Moustérien*, *Solutréen*, and *Magdalénien* divisions have been found *in situ*, superposed as in the French stations, and according to him his classification could be adopted for the English prehistoric stations. Is that the opinion of the English authors who have most recently written on the matter, and is it possible to make a classification founded on the objects of the human prehistoric industry, parallel to the palæontological and stratigraphical classifications? EDMOND BORDAGE.

Muséum d'Histoire Naturelle de Paris, August 2.

At Portrush.

BEING on holiday (at Portrush) in the second week of August, I discovered growing on the sand dunes there the following species, bearing beautiful pure white blossoms. I found several patches of each:—

Thymus Serpyllum (wild thyme); *Prunella vulgaris* (self-heal); *Gentiana campestris* (field gentian); *Erica Tetralix* (cross-leaved heath).

Also the wild strawberry, bearing abundantly white fruit. Are these cases of reversion or of adaptability? Moths were very plentiful all over the dunes. JAMES RIGG.

18, Wilton Drive, Glasgow, Aug. 18.

Origin of Idea that Snakes Sting.

WILL you kindly inform me as to the origin of the idea that snakes sting? Froude, in "The English in Ireland," page 356, vol. i., writes: "The clergy started as if stung by a snake." Archdeacon Farrar, in "Darkness and Dawn," uses the metaphor of snakes stinging. Sir T. Browne ("Vulgar Errors") says "That snakes and vipers sting," &c., &c., "is not easily to be justified. It is not fair to bring in Shakespeare as to a matter of natural history. CYRIL FRAMPTON.

July 29.

ON THE RELATIVE CONTAMINATION OF THE WATER-SURFACE BY EQUAL QUANTITIES OF DIFFERENT SUBSTANCES.

THE experiments of Lord Rayleigh and Prof. Roentgen on the thickness of the invisible films of oil on contaminated water-surfaces led me to repeat these measurements by a somewhat different method, which may perhaps be worth describing, and at the same time to compare the contaminating effect of various substances.

In order to divide very small masses exactly I chose the course of Lord Rayleigh[1] of transferring the contaminating substance to the water-surface by means of a volatile solvent. But instead of ether I used *benzine*, and let the drops of the solution evaporate *directly from the water* instead of vaporizing them on a metal plate and then immersing this, as Lord Rayleigh did.

As a fixed condition of the water-surface Lord Rayleigh chose the tension when the movements of camphor fragments are stopped. Still more suitable for my purpose, however, I found another smaller degree of contamination, which is always to be fixed with great exactness. I mean *that degree at which the tension just begins to sink*. As I have already explained (NATURE, vol. xliii. No. 1115, p. 437) the sinking of tension does not begin gradually from the very commencement of contamination, but *abruptly*, when the latter has arrived at a certain value, and then the falling of tension takes place very rapidly. The state of constant tension I have called the normal and that of variable tension the anomalous condition.

My task was therefore to examine how much of a substance is required to make a surface of a given size enter the anomalous state or to find the area of a surface made anomalous by a given mass of the substance. The latter method was generally preferred, for it was more convenient to me.

The observations were made with the adjustable trough and balance[2] described in NATURE, March 12, 1891, p. 437, and were as follows:—

Of the substance to be tried 13 mg. were dissolved in 300 ccm. of benzol. Then the trough being filled with water and the surface made as clean as possible by sliding the partition all over the length of it several times, the solution was transferred to the surface in drops, each of which had a volume of 31 cmm. or about 1/9600 of the whole solution and thus contained 0·001354 mg. Four drops were introduced each time in order to equalize accidental irregularities of size. When the evaporation of the benzol was finished I diminished the length of the surface till it became anomalous, and this length was noted. Then immediately other four drops were introduced, again measured, and so on. After two or more observations the surface was cleaned anew, but generally the first length was observed to be a little too large on account of the imperfect purity of the surface.

A sufficient number of observations having been thus made, the original contamination of four drops of the benzol used was measured in the same way; by subtracting this from the contaminating effect of the solution I got the effect of the oil or other substance purposely dissolved.

---

[1] Proc. of the Royal Society, 1890, vol. xlviii., No. 293, p. 127.

[2] For the purpose of actual measurements of surface-tension, I have constructed another instrument of larger dimensions; but to indicate only a slight variation of tension, any sensible balance with an adhering disc or wire-ring of any shape and size may be employed.

Thus with three solutions of Provence oil of equal concentration I got the length of the surface rendered anomalous by the oil contained in four drops:—

Solution I., 8·3cm.; Sol. II., 7·8cm.; Sol. III., 7·7cm.

For the sake of verification the other method, viz., counting the drops required for making the whole surface of the trough anomalous, was also employed. By this course the effect of four drops was obtained as follows:—

Solution I., 8·0cm.; Sol. II., 7·9cm.; Sol. III., 7·7cm.

The close agreement of the two methods proves that the strip of plate, simply laid across the trough, is sufficient to separate normal surfaces.

Another trial with an *ethereal* solution of olive-oil gave 7·1cm., if the somewhat different size of the drops be regarded; but I preferred benzine, because its original contamination was in most cases only between 1·3cm. and 2·5cm., whilst that of ether amounted to 4 to 6cm.

The mean of the lengths got by the three solutions was 7·9cm., and by this combined with the width of the trough = 5·8cm., we obtain the area of the surface made anomalous by 1mg. of Provence oil:

$$\frac{7{\cdot}9 . 5{\cdot}8}{4 . 0{\cdot}001354} = 8460 \text{ qcm.}$$

or a density of 0·000118mg. per qmm. at the beginning of the anomalous state.

In the following table are collected the results obtained with different substances:—

Substance.	qcm. per mg.	mg. per qcm.
Provence oil	8460 ...	0·000118
Ordinary olive oil ...	8565 ...	0·000117
Oleine [1]	8137 ...	0·000123
Rape-seed oil	7388 ...	0·000135
Poppy oil	8994 ...	0·000111
Tallow	9636 .	0·000104
Spermaceti	5568 ...	0·000179
Stearic acid	4711 ...	0·000212
Resin (colophony) ...	8105 ...	0·000123
Turpentine oil (clear) ..	107 ...	0·009346
Turpentine oil (older) ...	2944 ...	0·000339

The table shows next that the mass required for lowering the tension is not the same with different substances, and on the other hand it affords an interesting comparison between fluid and solid bodies. If the cause of the lowered tension be a film of greasy fluid spread over the surface, the contaminating effect of solid bodies can only be explained by small quantities of such fluids present on the surface or in the interior of the solid. This may be so in many cases, but the effect of stearic acid and spermaceti is such as if more than half their weight consisted of oil. The strong effect of colophony, although this did not dissolve entirely in benzine, and the result that tallow acts more strongly than an equal weight of oleine, its fluid component, also appear to me very remarkable.

After this it seems to me very probable that the contaminating substances *are not spread in coherent films at all*, but rather in a state of very fine distribution between the superficial water-molecules, that must be named either *emulsion* or *solution*.

However, only certain organic substances seem to be capable of forming surface-solutions of this kind, whilst the effect of metals and salts, formerly observed by me, was due to incomplete cleanness of the bodies, as later researches have proven.

Finally I will add some remarks on the thickness of the hypothetical oil-films. The thickness calculated from my observations with olive oil is at the beginning of the anomalous state 1·3 $\mu\mu$. In order to derive from this number the thickness at any other condition of the surface, it needs only to be multiplied with the relative contamination corresponding to that condition, that is, with the ratio of the surfaces. So we get at the smallest relative contamination measurable in my apparatus = $\frac{1}{35}$ a thickness of the film = $37 . 10^{-3}$ $\mu\mu$.

For measuring the relative contamination in the anomalous state, a special mode of procedure was required on account of the imperfect separation of surfaces by the partition. For that purpose I put on the surface that is to be contracted a [-shaped swimming wire, a little shorter than the width of the trough, and by the situation of this mark, following exactly every movement of the surface, I measured the relative length of the latter, instead of reading it from the partition itself.

The ratio in which the surface must be contracted in order to arrive at the tension at which camphor comes to rest, was very different with various substances, for an instance with stearic acid = $\frac{5}{3}$, oleine = $\frac{18}{11}$, ordinary olive oil = 5, and with Provence oil the tension in question could not be reached at all, except when the oil was standing on the water in visible drops or films. The calculated thickness of the film at the stopping of camphor movements would be with oleïn = 2·13 $\mu\mu$, ordinary olive oil = 6·5 $\mu\mu$, and with Provence oil still greater, if this liquid were spread equally. A very precise specification of the sort of oil used therefore appears to be necessary, if observations concerning this point are to be compared.

AGNES POCKELS.

[1] A brown-looking liquid sold under this name in the drug stores.

NOTES.

THE Federated Institution of Mining Engineers will hold its annual general meeting in North Staffordshire on Wednesday, September 7, in the large hall of the First Shropshire and Staffordshire Artillery Volunteers, Shelton. Both on that and on the following day visits will be made to various works and places of interest.

THE Committee appointed to consider whether a national aquarium should be established in Sydney have presented a full and interesting report to Mr. F. B. Sutton, the New South Wales Minister for Public Instruction. They strongly recommend that "a commodious building of a substantial and not unsightly character" should be erected, to contain a large series of tanks constituting the public aquarium, with experimental tanks for researches on fish-breeding, &c., in connection with the fisheries of the colony, and laboratories for scientific investigation. It is calculated that the "initial cost" would be about £10,000, and that an annual amount of about £1200 would be needed for salaries and for purchases, repairs, and other incidental expenses.

IN response to an invitation from President G. Stanley Hall, of Clark University, a number of psychologists met from various institutions at that University, Worcester, Massachusetts, on July 8, for the purpose of forming an American Psychological Association. Prof. G. S. Fullerton, of the University of Pennsylvania, presided. After some general discussion on the form of organization the entire matter was referred to a committee. Sessions were held in the afternoon and evening, at which papers were read by Profs. Jastrow, Sanford, and Bryan, and Doctors Nichols, Krohn, and Gilman. It was decided in response to an invitation from Prof. Fullerton to hold the next meeting of the Association in Philadelphia, at the University of Pennsylvania, on Tuesday, December 27. Prof. Jastrow was appointed secretary to provide a programme for that meeting. He asked the co-operation of all members of the Association for the section of psychology at the Chicago Exhibition, and invited correspondence on the subject.

DR. VON LENDENFELD, at one time assistant to Prof. Lankester at University College, Gower Street, has been appointed to the chair of zoology at the University of Czernowitz, rendered vacant by the death of Prof. V. Graber.

PROF. DR. CHARLES BERG has become director of the National Museum at Buenos Ayres, in the place of Prof. Dr. Hermann Burmeister.

THE Council of the Institution of Civil Engineers has issued a list of subjects on which it invites original communications. The list, it is explained, is to be taken merely as suggestive, not in any sense as exhaustive. The Council points out that it has power to award to the authors of papers premiums arising out of special funds bequeathed for the purpose. No award will be made unless a communication of adequate merit is received, but more than one premium will be given if there are several deserving memoirs on the same subject.

THE twenty-third session of the German Anthropological Congress, which was held at Ulm early in August, was in every way most successful. At the first meeting one of the most prominent speakers was Prof. Ranke, who spoke of the need for a German National Museum. He recognized the value of the museums at Mainz and Nürnberg, but urged that a genuinely national institution ought to be established, and that the proper place for it is Berlin. At this meeting an interesting discussion on the so-called Kannstadt race was opened by Dr. von Hölder. The opinion of the meeting was that the characteristics of the famous Kannstadt skull are found in some persons of the present day, and that the skull is not one that has come down to us from prehistoric times. Prof. Virchow, who took part in the discussion, uttered a general warning as to the necessity for caution in attributing high antiquity to human remains. On the following day a paper on the anthropological position of the Jews was read by Dr. von Luschau. His main points were that the Jews are a mixed race, and that in some of their physical peculiarities (such as the form of the nose) they resemble the Armenians more closely than any people of purely Semitic origin. Prof. Kollmann dealt with the question of the origin of the European peoples, and Prof. Virchow spoke of the fact that the traveller Vaughan Stevens has found in the interior of Malacca a genuine Negrito stock, and has sent skulls and specimens of hair. At the third meeting one of the best papers was by Dr. Boas, on the organization of anthropological research in North America. It was decided at this meeting that the next session of the Congress would be held at Hanover in 1893. Scientific excursions were made to Blaubeuren and Schussenried, where traces of lake dwellings have been discovered, and to Sigmaringen and Schaffhausen.

THE causes of the St. Gervais disaster are being gradually elucidated. A very interesting paper describing a visit to the small Téte-Rousse Glacier is contributed to *La Nature* (August 20) by M. Vallot, director of the new Mont Blanc Observatory. At the end of the glacier, on a steep face of rock, he and M. Delebuque found an enormous arching cavity, filled recently (it would appear) with ice which had been shot out by some internal force. They entered the cavern, and observed traces of an interior lake. A passage, strewn and overhung with blocks of ice, led up to an open space, a sort of huge crater, with walls of white ice, absolutely vertical. It was about 270 feet long, and 133 feet broad and deep. M. Vallot and his friend returned by the way they entered, and examined this crater from above. Their opinion is that a lake had been formed at the bottom of the glacier, and the crater, gradually accumulating through obstruction of the orifice of outflow, had undermined the ice-crust over the upper cavity. This at length collapsed, exerting enormous pressure on the water, which pressure, transmitted to the lower grotto, burst the glacier, throwing out the anterior part on the steep rocky slope. Thus is explained the enormous quantity of water precipitated into the valley, carrying in its passage the soil of the banks, and forming a torrent of liquid mud mixed with ice blocks and rocks. M. Vallot estimates that about 100,000 cubic metres of water and 90,000 of ice issued from the glacier. On reaching the Baths the torrent may have been 300,000 cubic metres. He supposes that the sub-glacial lake may form again, and the remedy would be to blast the rocky bottom so as to provide an escape for the water; a work which should be done speedily to be of use.

THE weather has been very unsettled during the past week, several low-pressure systems having passed over our islands from the westward, accompanied by very heavy rain, especially in the southern, northern, and western parts of the country. Between mid-day of Saturday and Sunday $1\frac{3}{4}$ inches fell in the south, being about three-fourths of the average fall for the month of August, and another heavy downpour occurred in the north and west on Monday night, two inches being measured in the west of Scotland, and $1\frac{1}{2}$ inches at Holyhead. The temperature has fallen considerably since the previous week, the daily maxima rarely exceeding 70° in the southern parts of the country, while in the north and west it has been considerably lower. The wind has reached the force of a gale on the coasts on more than one occasion during the week, and on Tuesday the centre of a rather deep depression lay over Ireland, while the sea was rough on nearly all coasts, the conditions being very threatening, with a prospect of further heavy rains. In southwest England the amount of rainfall from the beginning of the year up the week ending August 27th, was still more than eight inches below the average, and the only district where the amount just exceeded the average was the northern part of Ireland.

THE New England Meteorological Society has issued a volume of Investigations for the year 1890 (reprinted from the Annals of Harvard College Observatory, Vol. xxxi. pt. I., 1892) containing a summary of the observations made at the Society's stations; reports were received from 172 observers during the year, also five-year tables of temperature and precipitation, by J. Warren Smith, with an introduction by W. M. Davis, Director of the Society. The title scarcely explains the real amount of work done, for at some stations there are many periods of five years, *e.g.*, at New Bedford (Mass.) the observations extend over 15 pentades (1816–1890). It has not been possible to keep to the same years in all cases, nor has any attempt yet been made to discuss the data.—The tornado at St. Lawrence (Mass.), of July 26, 1890, by Helen Clayton. This storm caused considerable loss of life and property. The distances between the points where destruction was reported seem to indicate that the destructive winds descended at times to the earth's surface at certain points, and after a short track rose again. Prof. Davis has written a preface to this paper, in which he discusses fully the characteristics of tornados.

THE Annual Report on the Royal Botanic Gardens, Trinidad, for 1891, contains a table showing the monthly and yearly rainfall values for thirty years ending 1891. The average yearly fall for that period was 65·91 inches. Mr. F. H. Hart points out that the rainfall shows a decrease at a seriously rapid rate, for, dividing the period into decades, the first decade shows a total of 7·12 inches more than the second, and the third shows another decrease of 9·56 inches on the second, or 16·68 inches on the first decade. This is a subject of the utmost importance to questions of forestry and water supply. He also points out that the rainfall is not so much affected as is generally supposed by the contiguity of Trinidad to the mainland, but more particularly to the course of the trade-winds which blow towards the continent of South America. It is a curious fact that it always rains at Trinidad with a high barometer. On June 25 last the observer states that it was not daylight until long past the proper hour, the readings at 9h. a.m. having to be taken by candle-light. The rain was heavy and continuous, and was accompanied by the *highest* barometer readings for the year.

"FIFTY Years of York Meteorology, 1841–1890," a paper contributed to the report of the Yorkshire Philosophical Society for 1891, by Mr. J. Edmund Clark, has been issued in pamphlet form.

SOME of the effects of the absence of light upon animal life were strikingly revealed, not long ago, on the reopening of an old mine near Bangor, Cal. In a dry slope connecting two shafts, one of the explorers was astonished to find a number of flies that were perfectly white, except the eyes, which were red; and directly afterwards he killed a pure white rattlesnake. The animals had lived in the dry passages, where they had been supplied with air but not with light. It is supposed that the flies were the offspring of some that had been imprisoned by the partial filling of the mine with water about thirty years ago, and that the snake, when quite young, had been washed down in a rain. A few of the flies were exposed to light in a glass case, and resumed the colours of ordinary house flies within a week.

A WHALING party is being fitted out in America for the purpose of obtaining a live whale for exhibition in the Fisheries department at the World's Fair at Chicago. If captured the whale will be confined in a tank and towed to Chicago by the way of the St. Lawrence river.

IT would appear that naphtha is poisoning the Volga, doing great injury to the fishing industry. Dr. Grimm says (*Messager des Pêcheries*) that the quantity of naphtha conveyed on the river rose from some 32 million kilogrammes in 1887 to nearly 50 millions in 1889. Most of this is carried in badly-made wooden barges, and there is a great deal of leakage into the river, about 3 per cent. on an average (it is estimated). Thus in the three years, 1887 to 1890, the Volga must have absorbed some three million kilogrammes of naphtha, without reckoning petroleum, of which there is a considerable (though less) leakage. Everywhere the fish are decreasing, and they quite disappear at places where boats stop. On the other hand, various fishes—the starlet of Astrachan, *e.g.*—living in the infected water, get a flavour of naphtha, and are no longer eatable. The naphtha also kills the infusoria, insects, flies, mosquitoes, &c., which serve as food for the fishes. In its spring floods the river spreads naphtha over the meadows, destroying the larvæ of those organisms. The thin layer of naphtha on the water hinders the larvæ from breathing. Further, the naphtha injures the vegetation in the meadows. Naphtha is found in such quantities on the land as to suffice for domestic use to the natives, who collect it. Dr. Grimm urges the necessity of taking steps to prevent the ruin of the Volga fisheries.

AMONG the most interesting Echinoderms collected by the United States Fish Commission steamer *Albatross*, on her voyage from New York to San Francisco, was a stalked Crinoid, which is described in No. 2, vol. xvii., of the Memoirs of the Museum of Comparative Zoology at Harvard College (January 1892). The material, consisting of portions of three specimens, was dredged in 392 fathoms off Indefatigable Island, one of the Galapagos group. During the last dredging trip of the *Albatross* an additional specimen was obtained off Mariato Point, in 782 fathoms. When this last specimen was taken out of the water it was of a brilliant lemon colour, with a greenish tinge on the sides of the arms and along the food furrows of the ventral surface. A coloured sketch of it is given from a drawing made on the spot by Mr. Westergren. Its base of attachment came up with a fragment of stem nearly 14 inches long. At the first glance Prof. Agassiz was inclined to regard it as a modern representative of Apiocrinus, but a more careful examination showed so many points of difference that he had to establish the new genus Calamocrinus for its reception, and it stands as *C. Diomedæ.* It is most closely allied to a large group of Mesozoic Crinoids, and it assists in making clear many points in their morphology. This genus has the orals greatly reduced, much as in Bathycrinus. It also possesses heavy perisomic plates, passing gradually into still stouter so-called interradial plates, in Calamocrinus, in no wise to be distinguished from the true interradials of Palæozoic Crinoids. Another structural feature is the limitation of the articular facet to the middle of the radial. This is an eminently embryonic character, and there are traces of it in some of the forms of Millericrinus described by De Loriol in his Jurassic Crinoids, especially in *M. milleri.* After a very detailed and masterly description of the stem, calyx, and arms of the species, Prof. Agassiz discusses the subject of the "Apical System of the Echinoderms," and "Of some of the Homologies of the Echinoderms." Thirty-two plates, some coloured, accompany this Memoir, which is inscribed as follows: "From the time the Crinoids which form the subject of this Memoir came into my hands, I have been in constant correspondence with my late friend, Philip Herbert Carpenter, regarding the many points of interest suggested by their discovery. I can now only have the melancholy satisfaction of inscribing to his memory a Monograph which I had hoped to dedicate to him as an expression of my admiration for his researches in a field where we had long been fellow workers."

M. DE LAPOUGE calls attention, in *La Nature*, to an interesting object he has found in one of a number of ancient graves he has been excavating at Gignac (Hérault). It is a finely-carved head of jade, representing a type of the yellow race. It evidently formed part of a statuette of a religious character, and the style shows that it must have come either from China or Japan. M. Sindhô is of opinion that the statuette was probably made in Japan a little before the Christian era, from a Hindu or Sinhalese model of Buddha. M. de Milloué thinks the head is that of Kouan Yin, a Chinese divinity, while M. de Rosny and M. Motoyosi attribute it to Mayadêvi, the mother of the founder of Buddhism. Whatever the object may be, M. de Lapouge is inclined to believe that it hung as an amulet around the neck of a Hun or Goth, and that the graves at Gignac belong to a cemetery of a West Gothic colony.

A VALUABLE essay on the Ainos of Yezo, by Mr. Romyn Hitchcock, is included in the report of the U.S. Museum for 1890, and has just been issued separately. It is based mainly on the author's personal observations. He has much that is interesting to say on the various aspects of the life of the Ainos, and his remarks are admirably illustrated. Mr. Hitchcock notes the remarkable fact that the Ainos have been very little influenced by the civilization of the Japanese, with whom they have so long been in close contiguity. The Aino, he says, has not so much as learned to make a reputable bow and arrow. Unable to affiliate with the Japanese, the Ainos "remain distinct and apart," and for that reason, in Mr. Hitchcock's opinion, are "doomed to extinction from the face of the earth."

THE second volume of Mr. J. Walter Fewkes's "Journal of American Ethnology and Archæology," has just been issued. The most important article in the first volume was an interesting account, by Mr. Fewkes, of "a few summer ceremonials at Zuñi Pueblo." The greater part of the second volume is devoted to a description, by the same writer of "a few summer ceremonials at the Tusayan Pueblos." Mr. Fewkes and his assistant, Mr. J. G. Owens, were admitted as priests by the Tusayans, so that the paper contains many details which have not hitherto been accessible to students. Mr. Fewkes also presents a report on the present condition of a ruin in Arizona called Casa Grande, and Mr. Owens describes various natal ceremonies of the Hopi Indians.

THE new number of the *Internationales Archiv für Ethnographie* (Band V., Heft 3) opens with a paper, in French, by M. G. van Vloten, on the flags used at Teheran in connection with the festival in memory of the martyrdom of the Imâm Huçeïn. M. Désiré Pector contributes (also in French) some observations suggested to him by the reading of a work by M. de Montessus on Pre-Columbian Salvador. Herr F. Grabowsky writes (in German) on the theogeny of the Dayaks.

THE following are the subjects of papers in the current number of the *Mineralogical Magazine*:—Minerals from the apatite-bearing veins at Noerestad, near Risör, on the south-east coast of Norway, by R. H. Solly (with a note on their occurrence, by A. L. Collins); on the pinite of Breage in Cornwall, by J. H. Collins; danalite from Cornwall, by H. A. Miers and G. T. Prior; mineralogical notes from Torreon, State of Chihuahua, Mexico, by Henry F. Collins; note on crystals of manganite from Harzgerode, by Frank Rutley; analysis of aragonite from Shetland, by J. Stuart Thomson; orpiment, by H. A. Miers. There are also reviews and abstracts; and Mr. Miers and Mr. Prior contribute a valuable index to mineralogical and petrographical papers, 1888.

WE have received from the Geological and Natural History Survey of Canada, Part 4 of "Contributions to Canadian Micro-Palæontology." The report consists of descriptions and illustrations of thirteen new and three previously known species of Radiolaria, collected by officers of the survey from the upper cretaceous rocks of North Western Manitoba, and has been prepared for publication by Dr. D. Rüst, of Hanover. Mr. Tyrrell, geologist in charge of the explorations in Manitoba, contributes a short introduction to the report.

BULLETIN No. 11 of the Imperial University College of Agriculture, Komaba, Tōkyō, has recently been published. It consists of the report of Dr. O. Kellner on the third year's "Manuring Experiments with Paddy Rice."

AMONG the contents of the June number of *Temehri*, the Journal of the Royal Agricultural and Commercial Society of New Guinea, are papers on "Twenty Years' Improvements in Demerara Sugar Production" (Part 2), "The Bats of British Guiana," "Guiana Gold," and "Our Birds of Prey." The number also contains many short notes of an interesting nature.

MR. S. GARMAN publishes a treatise on the fishes of the families Cyclopteridæ, Liparopsidæ, and Liparididæ, in the Memoirs of the Museum of Comparative Zoology at Harvard College (Vol. xiv., No. 2, April 1892). Though several of the rarer forms of Discoboli are not represented in the collections of the Harvard Museum, yet it possesses so many duplicates of several species, in addition to rare and some undescribed types of others, that it presented great facilities for a study of the group, of which Mr. Garman has well availed himself. Prof. F. W. Putnam had at one time intended to write a history of the group, and many drawings had been some years ago prepared for it by Mr. Roetter; these drawings have been utilized in the present memoir, and the work has been made more complete by the drawings of the young stages of several of the species, contributed by Prof. A. Agassiz. After a short introduction there is a history of the distribution of the species, followed by one on the history of the genera from the times of Pliny, Gesner, and others, and then a description of the recognized genera and species, of which the following is a summary. *Cyclopterus lumpus*, Linn.; *Eumicrotremus spinosus*, Mull.; *E. orbis*, Gthr.; *Cyclopteroides gyrinops*, gen. et spec. nov. (St. Paul's Island, Alaska); *Cyclopterichthys ventricosus*, Pall.; *C. amissus*, Vaill.; *Liparops*, gen. nov. established for *Cyclopterus stelleri*, Pall.; *Liparis montagui*, Don.; *L. mucosus*, Ayr.; *L. calliodon*, Pall.; *L. liparis*, Linn.; *L. antarctica*, Put.; *L. agassizii*, Put.; *L. tunicatus*, Reinh.: *L. steineni*, Fisch.; *L. pulchellus*, Ayr.; *L. pallidus*, Vaill.; *Careproctus micropus*, Gthr.; *C. major*, Fabr.; *C. gelatinosus*, Pall., *C. reinhardi*, Kroy.; *Paraliparis rosaceus*, Gilb.; *P. bathybius*, Col.; *P. liparinus*, Goode; and *P. membranaceus* Gthr. *Careproctus longifilis*, spec. nov., and *Paraliparis fimbriatus*, spec. nov., are also indicated, but will be described at length in the forthcoming report of the "U. S. Fishery Commission."

SOME experiments have recently been made at the New York Agricultural Experiment Station upon the possible effect of long-continued applications of a copper sulphate spray used as a fungicide (Bulletin 41). Two soil mixtures were used, one containing 5 per cent. and the other 2 per cent. of copper sulphate. These quantities are comparatively so enormous that useful practical conclusions cannot yet be drawn, though some of the results have proved interesting. Seeds of plants representing widely differing natural orders were planted in these soils, and at the same time an equal number of the same kinds of seeds were planted for checks in similar soil to which no copper sulphate was added. Care was taken to select good seed, and to give the soil mixtures, and checks exactly similar conditions and treatment. In the soils containing sulphate of copper more seeds germinated in almost every case than in the soils containing no copper. The average length of time required for germination was greatest in the copper soils. The foliage of plants grown in the copper soils was of a deeper green and darker with the 5 per cent. soil mixture than with the 2 per cent. one, but although darker the leaves were smaller and the height of the plants and the yield of fruit very much less than in the case of plants grown under normal conditions. Peas grown in the 2 per cent. soil mixture seemed to be more vigorous for the first few weeks than the check plants grown in untreated soil; they also came to maturity earlier, but finally showed a dwarfed appearance, and the yield was less than with the check plants, being little more than one-half the yield under normal conditions. In the 5 per cent. soil mixture peas gave a yield only one-seventh of that from untreated soil. In the case of all plants grown in the soil mixtures the roots were very small and ill-developed. Analysis of the tops of tomatoes grown in the 5 per cent. soil showed in the air-dried substance ·06 per cent. of copper, proving conclusively that these plants can take up sulphate of copper by their roots. Analyses were made of berries and stems from vines which had been sprayed with copper compounds, and although the amount of copper found upon the stems varied, that found on the grapes was practically constant, and amounted to 1/120th of a grain per pound of grapes, this quantity being considered quite negligeable and harmless.

THE additions to the Zoological Society's Gardens during the past week include two Rhesus Monkeys ♂ ♀ (*Macacus rhesus*) from India, presented by Mr. J. Hall-Browne and Mr. Rivers respectively; four Virginian Foxes (*Canis virginianus*) from California, presented by Mr. Edward Chauvenet Holden; two Ogilby's Rat Kangaroos (*Hypsiprymnus ogilbyi*) from Australia, presented by Mr. John W. Roche; a Ruffed Lemur (*Lemur varius*) from Madagascar, deposited by Captain Marshall, F.Z.S.; three Tigers ♂ ♀ ♀ (*Felis tigris*) from India, deposited by Messrs. William Watson and Co.; a Blue and Yellow Macaw (*Ara avarauna*) from South America, presented by Mr. R. Larchin; ten Spanish Blue Magpies (*Cyanopolius cooki*), and two Ravens (*Corvus corax*) from Spain, deposited by Lord Lilford, F.Z.S.; two Fringed Chameleons (*Chamæleon tæniobronchus*) and a Lobed Chameleon (*Chamæleon parvilobus*) from Natal, presented by Mr. Charles W. Heaton; a Black Iguana (*Metopoceros cornutus*) from West Indies, purchased; six African Scorpions (*Scorpio*, sp.inc.) from South Africa, presented by Mr. J. F. Hawtayne.

OUR ASTRONOMICAL COLUMN.

PHOTOGRAPHIC MAGNITUDES OF NOVA AURIGÆ.—*Astronomical Journal*, No. 269, contains the results of Mr. J. M. Schaeberle's work with regard to the determination of the photographic magnitudes of stars, including also that of Nova Aurigæ. The method he has adopted differs from those used by former observers in that the photographic magnitude of a star for any exposure-time is expressed "as a function of the equivalent theoretical aperture which a standard star (Polaris in this case) would require to make the same impression on the plate in the same time." The particular form which the expression, as obtained from this investigation, assumes enables one, after having once adopted the photographic magnitude of the standard star, to determine the theoretical photographic magnitude of any other star without any reference at all to the visual magnitude. As this method had only been applied to bright stars, the appearance of Nova Aurigæ suggested a further trial for stars of less magnitude which were visible only in large instruments. On the plates, which were each night exposed, three stars in the region of the Nova, the images of which resembled somewhat that of the Nova in form, size, and density, were selected for the sake of comparison. The magnitudes of these comparison stars were then determined by direct measurement of their images on the standard positive plate, this plate being a second positive from the original negative. The resulting photographic magnitudes for the month of February showed that the light of this new star fluctuated very considerably, confirming the visual observations.

The following list gives the theoretical magnitudes as obtained in this way, the mean time at Mount Hamilton being also added. The exposures up to March 10 were all moderately short, varying from 2 to 128 seconds.

COMPARISON STARS OF THE PLANET VICTORIA.—Dr. Gill, in *Astronomische Nachrichten*, Nos. 3107-08, communicates an article on the definite places of the stars used for comparison with the planet Victoria in the observations for parallax made in the year 1889. The positions of these stars are now, as he says, "more accurately known than those of any other group of stars in the heavens," and he suggests that they should be advantageously used for the determination of optical distortion and scale values of photographic telescopes, and for testing the various methods for the "raccordement des plaques." The positions of the thirty-seven stars are based on 3766 meridian observations of right ascension, and 3771 meridian observations of declination, together with several other observations made with the heliometers at the Cape, Yale, and Göttingen, amounting to 1867 measurements of distances, and 151 position angles. In the first tables which Dr. Gill here gives, are shown the definite places for the Victorian comparison stars computed for the Equinox 1889·90, and Epoch 1889·55. Owing to the comparatively large quantities that the probable errors of the proper motions amount to, Dr. Gill mentions that it is desirable to obtain photographs for determining scale-value distortion, &c., as soon as possible. Table 2 consists of a comparison between the distances as obtained from definite co-ordinates, and these as measured by Gill, Finlay, Jacoby, Chase, Schur, and Ambronn with the heliometer.

INTERNATIONAL TIME.—In a small pamphlet, published by Mr. Edward Stanford, a scheme for a systematic regulation of time is discussed by Major the Hon. E. Noel. The principle on which the system he proposes is based is the same as that which is at present in use on the American continent. It consists in dividing the earth's surface up into time-zones each covering fifteen degrees, so that they will differ from one another by one hour. In considering the question of the initial-time meridian, there are many points which have to be well borne in mind. In the first instance there must be a first-class observatory, on which every one could depend; secondly, the contra-meridian, *i.e.*, that half of the initial meridian in the opposite hemisphere, must fall in a convenient place, by which is meant that it must not cut through a continent or any large tract of land. Another important consideration is the arrangement of the time-zones, which must, if possible, be conveniently related to the longitude boundaries as are shown in our maps. Taking these points into account, Major Noel retains Greenwich as the initial for longitude, but selects Rome as our initial for time. On this basis he discusses this scheme with reference to each individual country. The only great country which this arrangement would not suit is France, for she, as is well known, keeps Paris time; a suggestion put forward here is that France should form a special zone, making her time exactly, instead of approximately, forty minutes after Rome. The folding diagram which accompanies this pamphlet shows a map of the world graduated on this system. From this one sees that the meridian of Rome traverses the centre of the Scandinavian Peninsula, coincides with Copenhagen, passes close to Leipzig, and between Berlin and Munich, while it cuts Italy from north to south. The western boundary of this zone, which is exactly on the fifth meridian west of Greenwich, passes between Italy and Spain, outside the western frontier of Germany, and skirts the west coast of Norway, while the eastern boundary also traverses convenient points for such a division of time. In considering the scheme as a whole, there is much to be said in its favour; but as such a question as this deals with so many nations, its development and final adoption cannot take place in a trice, but can only be brought to a head after many years' deliberation and debate.

COMET SWIFT (MARCH 6, 1892).—The ephemeris of Comet Swift is given in *Edinburgh Circular*, No. 29, and has been computed from elliptic elements supplied by Herr Berberich. This comet in large telescopes is quite a conspicuous object, while in smaller ones it is still visible. The following ephemeris we take from the above-mentioned source:—

Ephemeris for Berlin Midnight.

1892.	R.A.	Decl.	Log Δ.	Log r.	Br.
	h. m. s.	° ′			
Aug. 31	0 42 35	+52 42·6			
Sept. 1	41 24	38·3			
,, 2	40 10	33·6	0·2693	0·3922	0·081
,, 3	38 55	28·5			
,, 4	37 39	22·9			
,, 5	36 22	16·9			
,, 6	35 4	10·5	0·2720	0·4004	0·077
,, 7	0 33 46	52 3·7			

Taking the comet's position for September 2, we find that it will lie very nearly 3½° south of α Cassiopeiæ, being in the prolongation of a line joining the stars λ and ζ of the same constellation.

GEOGRAPHICAL NOTES.

THE Berlin Geographical Society are preparing for publication one of the most valuable mementoes of the Columbus celebration, in the form of a magnificent atlas, containing amongst other early maps a series of hitherto unpublished delineations of the Atlantic of very early date. These maps have been discovered in manuscript in Italian libraries, where they were copied by a young German geographer of great artistic power. They will be published with all the brilliant colouring of the original illuminated MSS.

IN the recent risings of the Arabs against European traders and officials on the Lomami in the Congo Free State, there is too much reason to fear that the veteran M. Hodister, Director of the Katanga Company in Africa, has lost his life. This is a disaster of a much more serious kind than the mere collapse of a trading company, for M. Hodister in the course of his long service in Central Africa had acquired a remarkable knowledge of the Arabs, and great tact and success in dealing with them. In his personal character he commanded the respect of all with whom he came in contact; courage he shared with many fellow-explorers, but his calmness in danger and serious earnestness in work are not too common amongst the Congo State officials or the leaders of caravans through the territory. M. Hodister was one of the first Belgian officers appointed on the establishment of the Congo Free State, and as an official, and later as the head of the Katanga syndicate in Africa, he has spent the best years of his life in opening up the Congo Basin.

THE Sixth International Geographical Congress having been fixed to meet at London in June, 1895, an organizing committee, of which Major Leonard Darwin is President, and Mr. J. Scott Keltie Secretary, has been appointed by the Council of the Royal Geographical Society. Circulars have been sent out calling attention to the fact that the meeting is to take place, and inviting suggestions. A provisional programme of the proceedings will be drawn up in the course of next year.

AN exhaustive bibliography of Socotra has just been published as a pamphlet of forty pages by M. James Jackson, the librarian of the Paris Geographical Society. Including references to maps, there are 176 entries relating to this island; many of these papers had almost passed into oblivion, and their recovery and systematic presentation is of much value.

SOME PROBLEMS IN THE OLD ASTRONOMY.[1]

IF a comparison were instituted between the position of the modern astronomer and that of his prototype on the plains of Chaldea, it would not be altogether to the disadvantage of the ancient student of the heavens. He stood at the gateway of the unexplored Uranian mysteries, unfettered by the dogmatic theories of a line of predecessors. From his own imagination he constructed hypotheses and theories, with no feeling of uncertainty about the priority of invention, and with little anxiety concerning the agreement of theory and observation. The modern questions that distract the astronomical world had no place among the thoughts that disturbed the tranquillity of his soul. He had not reached that critical epoch when he must choose between the "old" and the "new" astronomy; and he was free from the harassing perplexity that besets the luckless astronomer of this age who seeks to learn the mysteries of the moon's motion, or strives to formulate the cause and the law of the variation in the terrestrial latitude. The iniquitous behaviour of the astronomical clock and level, combined with the possible, but unknown, influences of temperature, were not then in league to vex his waking hours and fill his dreams with illusory solutions that ever floated just beyond his grasp. He was not obliged to search the ancient records in musty volumes and strain the limits of conjecture in the interpretation of careless observations and imperfect memoranda; in short, he was a happy man, free to work in any direction, and not liable to be called upon from time to time to amuse or to instruct his fellows, or even to weary them, with prosy discourse on his own work or a stale *résumé* of astronomical progress.

Unfortunately for us, we live in an age when astronomy is no longer a simple subject, stimulating the imagination by the nightly display of stellar and planetary glories, and involving in its study only the elements of geometrical analysis. Within the last fifty years the science has been separated into many divisions; and within a few years several of these branches have assumed new phases. As a result of this continued division, the range of study and investigation has spread beyond the efficient grasp of any individual, and specialists are rising up in all directions.

It has been the custom for the presiding officer of this section to present, on the first day of the annual session, an address setting forth either the progress in general astronomy or in some branch of the science, or the history or development of some department of mathematics, each confining himself to his own special branch of scientific work.

It has seemed to me that a formal statement, to this section, of the general progress of astronomy within the last year or the last decade, would be to lay before you a mass of data with which you are already familiar. This view of the case has led me to attempt the presentation of the importance of one branch of astronomical work in which for several years I have taken a deep personal interest, and which, owing to the present tendency towards specialization, is likely to suffer from serious neglect.

It is not many years since we first heard of the distinction between the "old" and the "new" astronomy, but in the comparatively short interval since those terms were first used the scope of physics has so expanded in all directions and so adapted itself to its new surroundings that we find it, in one department at least, casting aside its former title and masquerading under the name of astronomy. That this departure has quickened the zeal of many students, stimulated the development of numerous and valuable modes of research, and resulted in grand and important discoveries, is one of the most gratifying scientific facts of this epoch. The direction of this new movement has followed rigorously the line of least resistance. Except in rare instances, that line of work which promises the quickest returns in the proper form for publication is most attractive to the young student of physics and astronomy, and the comparatively inexpensive apparatus required for the simpler astro-physical work is apt to lead him in that direction. The new and important changes that have been wrought within a few years in the methods of teaching and in the laboratory work in physics, together with the apparent ease with which an account of a few hours' labour with the spectroscope or camera may be spread attractively over several printed pages, have doubtless had their influence in leading the candidates for honours into the new fields of astro-physical research.

The advance in the development of methods of research and the improvements in apparatus are so rapid, and the field is so broad and increasing, that constant vigilance is necessary to keep even in touch with the progress of the "new" astronomy. One of the most striking examples of the achievements in this new line of work has resulted from a skilful combination of the spectroscope and the camera in the determination of stellar motion in the line of sight with a remarkable linear exactness.

The limits of this address would scarcely suffice to simply name the problems now under discussion by the more modern methods, without essaying even a cursory review of their importance or their bearing on current scientific investigation; and yet, from the true astronomical point of view, all of these questions are at least secondary to the fundamental problems of finding the true position of the solar system in the stellar universe and determining the relative positions and motions of those stars that, within the range of telescopic vision, compose that universe.

To this latter phase of our science I ask your attention for a few minutes. These problems still lie at the foundation of the "old" astronomy and cannot be relegated to the limbo of useless rubbish or to the museum of curious relics, not even to make room for the new-born astro-physics. On this foundation must rest every astronomical superstructure that hopes to stand the tests of time and of observation, and the precision of the future science depends rigorously upon the accuracy with which this groundwork is laid.

This work was begun in the sixteenth century, but, in spite of all the improvements in apparatus and in methods of analysis and research, a really satisfactory result has not yet been reached. There is no more fascinating phase of the evolution of human thought and skill in the adaptation of means to ends than is found in the development of the mathematical and instrumental means for the determination of the positions and motions of the bodies included in the solar system. Accuracy in astronomical methods and results did not exist, even approximately, until after the revival of practical astronomy in Europe about the beginning of the sixteenth century; and, before the end of that period, the crude instruments of the early astronomers reached their highest perfection in the hands of the skilful genius of Uraniborg.

---

[1] Address delivered before Section A of the American Association for the Advancement of Science, by Vice-President J. R. Eastman.

The invention of the telescope, the application of the pendulum to clocks, the invention of the micrometer, the combination of the telescope with the divided arc of a circle, the invention of the transit circle by Roemer, with many improvements in minor apparatus, distinctly stamp the seventeenth century as a remarkable period of preparation for the achievements of the next century.

From the standpoint of the modern mechanician the instruments at the Greenwich Observatory in Bradley's time were very imperfect in design and construction, and yet on the observations obtained by his skill and perseverance depends the whole structure of modern fundamental astronomy. The use of the quadrant reached its highest excellence under Bradley's management.

The next advance, the real work with divided circles, began at Greenwich in 1811, under the direction of Pond. Since that epoch, theory and observation have held a nearly even course in the friendly race toward that elusive goal perfection; and the end is not yet. A careful, but independent, determination of the relative right ascensions of the principal stars, supplemented by a rigorous adjustment of such positions with regard to the equinoctial points, and a similar determination of the relative zenith or polar distance of the same bodies, finally referred and adjusted to the equator or the pole, seem in this brief statement to be, at least, simple problems. If, however, we examine the conditions in detail the simplicity may not appear so evident; and this characteristic may prove to be one reason why this important branch of astronomical research is now so generally neglected.

In the first place, it must be understood that such an investigation cannot be completed in a few months. At least *two* and preferably *three* years' work in observing are necessary to secure good results. Skilled observers, and not more than two with the same instrument, are absolutely necessary. Such work cannot be confided to students or beginners in the art of observing, or to observers who have acquired the habit of anticipating the transit of a star. The telescope and the circles, the objective and the micrometer, the clock and the level must be of the best quality, for imperfections in any of these essentials render the best results impossible. A thoroughly good astronomical clock is the rarest instrument in the astronomer's collection. It is not sufficient that a clock should have a uniform daily rate, the rate should be uniform for any number of minor periods during the twenty-four hours. The absolute personal error in observing transits should be determined at least twice a week, and when it is not well established it should be found every day. The level error should be found every two hours, and the greatest care should be exercised in handling this important instrument. The division marks should not be etched on the level tube unless the values of the divisions are frequently examined, for, sooner or later, such tubes become deformed on account of the broken surface, and are then worthless.

In the determination of zenith distances the effect of refraction plays such an important part that no work can rightly claim to be fundamental until the local refraction has been carefully investigated, and special corrections to the standard tables, if necessary, have been deduced for each observing station. The ordinary mode of observing temperature is quite inadequate to the importance of the phenomena. These observations should be made as near as possible in the mass of air through which the objective of the telescope is moved, and also in the opening in the roof and the sides of the observing room where the outside air comes in contact with that in the building. The thermometers should all be mounted, so that they may be whirled in that portion of the air where the temperature is desired, and they should be tested at least once a year to determine the change in the position of the zero of the scale. But a complete list of the things to be done, and of the errors to be avoided, are too voluminous for this occasion, and are not necessary to show the complex character of the problem; the suggestions already made must suffice.

For many years an immense number of observations of the larger or the so-called standard stars have been made at the principal observatories, for different purposes and with varying degrees of accuracy, but it is not certain that the work of the last thirty years, with all the advantages of improved apparatus, has resulted in more exact determinations of even the relative right ascension of such stars. There can be no doubt that the chronographic registration of star transits has given more accurate results for the smaller stars, but I think it is equally true that, in the case of first and second magnitude stars at least, no improvement has been made in accuracy.

With double threads it is possible to observe the zenith distances of such stars with a fair degree of precision, because the operation is one of comparative deliberation, and the centre of the mass of light can be placed midway between the threads with little difficulty. But the attempt to note, with a chronograph key, the instant when a swiftly-moving and irregular mass of light, like α Canis Majoris or α Lyræ, is bisected by a transit-thread, is an operation that rises but little above the level of ordinary guesswork. Transits of first and second magnitude stars cannot be observed with an objective of more than four inches aperture with the desired accuracy, unless the apparent magnitude is reduced, by means of screens, to that of a fourth or fifth magnitude star. It is necessary in this connection to avoid confounding the methods employed in the observations of the bodies of the solar system with those for obtaining fundamental places of the stars. The observations of the Sun, Moon, Mercury, and Venus with a transit circle are, from the unavoidable conditions, necessarily uncertain to a degree even beyond the probable error involved in the observations of the large stars. In spite of these unfavourable conditions, however, the continued observations of these bodies at the principal observatories for many years have produced the most valuable results, even when the work on the standard stars, on which their results depend, has no claim whatever to a fundamental character.

In geographic exploration the first endeavour is to secure approximate positions of salient points from a rapid reconnoissance. This is followed by more careful work, fixing the observing stations with that degree of precision which ensures good results. Finally, the highest qualities of skill and science are combined to exhaust all available means to reach the greatest attainable accuracy. In the exploration of the heavens, the first two of these steps have already been taken, and most of the stars of the larger magnitudes have been so well observed, that the accuracy of their positions is not only far higher than is required by the greatest skill of the navigator, but it is equal to all the demands of ordinary practical work. It is the next step which challenges the skill of the mechanician, the observer, and the computor; and astronomers cannot rest at ease until all known resources have been exhausted in the attempt to reach the best results. It is not a very difficult matter to fix the position of stars within a range, in the individual observations, of three or four seconds of arc; but that degree of accuracy is not sufficient for the more exact problems of astronomy, and it falls far short of what is required in the important discussions of solar and stellar motions.

Bradley's observations furnish the data for Bessel's "Fundamenta Astronomiæ," and many astronomers have since attempted by reductions to obtain improved positions for Bradley's stars. The value of these observations in the development of modern astronomy can hardly be exaggerated. Their importance in the determination of stellar proper motions increases with the lapse of time, and yet the accuracy of the original observations was far inferior to that obtained in ordinary routine work with modern methods and improved instruments.

Fundamental catalogues of stars have notably increased since the "Fundamenta Astronomiæ," but the demand has not yet been satisfied. The catalogues of declinations or north-polar distances are more numerous than those of right ascension, evidently because, for many reasons, independent declinations are more readily determined.

There is probably no collection of the right ascension of the large stars that has attained, or justly deserved, a higher reputation than the Pulkowa Catalogue. The observations on which this catalogue is founded were made by Schweizer, Fuss, Lindshagen, and Wagner, at the Pulkowa observatory between 1842 and 1853. The observations were reduced by the several observers, thoroughly discussed by Wagner, and published in 1869. Only one observer was employed at any period. As these results have received high praise for their accuracy, and for their freedom from systematic errors, it may be of some interest to consider briefly, and in a general way, the character of the data on which the results depend.

The objective of the transit instrument with which these observations were made, had a focal length of 8 feet and 6 inches and a diameter of 5·85 inches. It was so constructed that the ocular and the objective could be interchanged. It was also reversible, and a part of the observations were made with the clamp east and the remainder with the clamp west. This construction permitted the observations to be made under four different sets of conditions, and for that reason the observed right ascensions of each star were arranged, for facility of discussion, in four separate groups.

An examination of the results in each group discloses some interesting facts that are worth considering somewhat in detail. The whole number of stars in the catalogue that are reckoned as standard stars, and are south of 70° north declination, is 365. Of this number 70 per cent. have a range, in the individual results, in at least one of the four groups, of two-tenths, or more, of a second of time. This range is between 0·20 and 0·29 for 142 stars; between 0·30 and 0·39 for 92 stars; between 0·40 and 0·49 for 15 stars; and 0·50 or more for six stars. The mean range for the 255 stars is 0·297. In general, the accordance between the individual results is quite good, but the discordance just mentioned sometimes occurs more than once in the collected observations of the same star, and these doubtful data have been used in deducing the standard places given in the catalogue. It is not necessary to look for minor discrepancies, for enough of appreciable magnitude have been cited already to warrant the conclusion that better observing can and ought to be done with modern instruments, and that the needs of astronomical science to-day demand a more comprehensive, and a more accurate, standard catalogue of right ascensions.

These remarks must not be interpreted as unfavourable criticism of the Pulkowa Catalogue, by far the best work of its period, but they are made simply to call attention to the fact that the present state of stellar astronomy and the direction which the investigations of the immediate future are likely to take, plainly require the most accurate fundamental catalogue of the standard stars that modern instruments and appliances, modern methods and the most skilful observers can produce. All of these conditions are essential, and they must be carefully co-ordinated to obtain the desired results.

It must be plain to every astronomer that the needed fundamental catalogue must be deduced from new observations. The reduction and the discussion of old observations of doubtful quality is a waste of time and energy. Under existing circumstances the greatest weight must be given to the observations. Neither amount of labour nor skill in computation can derive results of the desired accuracy from careless, incomplete, or incorrect observations. An attempt on the part of the computer to apply any system of theoretical weights, either simple or complex, to such observations is almost certain to lead, at least, to self-deception; and the safe as well as reasonable rule in such case would be to use the weight zero.

One example may serve to illustrate the effect of dealing continuously with old observations. In standard star positions the four principal national ephemerides are not only not in accord with each other, but they generally do not exhibit results even from the few best modern observations. The many discrepancies of varying magnitude in these volumes present with marked emphasis the undesirable results arising from the custom of "threshing old straw."

The data on which these several ephemerides are founded are the common property of all astronomers, and no one can claim the exclusive use of any published observations; and yet national pride or national obstinacy, which is sometimes mistaken for the nobler sentiment, or some computer's pet scheme or system of combination, has led to the adoption of a variety of assumptions in the interpretation and treatment of the original data until our standard ephemerides are so complex in their structure that the exact details of their preparation are practically unknown outside their respective computing offices. The accuracy of the star positions is unchecked by any recent fundamental observations, and they lack that trustworthy character that should inhere in a system intended to serve as a basis for even good differential work.

If this character were wholly satisfactory, we should soon see the representatives of astronomy, geodesy, and geology gathering about the zenith telescope, confident of reaching some definite conclusion in regard to the variation of terrestrial latitudes by the systematic use of this simple instrument. But the accurate star positions do not exist, and under the present conditions the most feasible plan for utilizing this instrument is to so arrange the observing stations as to eliminate the effect of errors in the star places.

If it be admitted that sidereal astronomy is worthy of further and more accurate study, that the needs of astronomical research at the present time and in the immediate future demand more exact positions of the standard stars, it may be desirable to consider briefly the status of those agencies to which we must look for the successful prosecution of such an investigation.

It is not an easy task to determine the exact number of active observatories in the world. Some published lists contain the names of all observatories, from the most expensive and fully equipped Government establishments to the temporary shelter that protects a small equatorial telescope, and perhaps a chronometer, which is kept by the owner for the amusement and possibly for the instruction of himself and his friends. A fair enumeration, however, would probably give a list of about 250 observatories sufficiently equipped to do some kinds of astronomical work. Of this number more than 20 per cent. are found in North America. In the equipment of these 250 observatories are to be found about sixty transit circles with objectives ranging from nine to about three inches. The quality of about one-fourth of these instruments is such that good results may be expected from their proper employment. To the latter class of instruments we are limited when we seek for the highest class of work now under consideration. If we take account of the modern subsidiary apparatus, and of the electric methods of recording transit observations and illuminating the different parts of the instrument, it does not seem extravagant to conclude that, if one third of the best transit circles were devoted for the next four years to observations for the formation of a fundamental star catalogue of right ascensions and north-polar distances, the aggregate result would be not only the best positions ever published, but it would be of the greatest value in the discussion of current, as well as future, astronomical problems. Unfortunately, however, we do not find any such number of instruments employed in fundamental work. At the present time there is no general fundamental work in progress in any portion of the world, and within the last thirty years there have been no results of that character to take the place of the Pulkowa determinations. This statement does not refer to observations of one ordinate only, or to those cases where several observers, both trained and untrained, are accustomed to observe in turn with the same instrument and their several results are indiscriminately mingled in such a way that critical discussion is out of the question. Several observers may work together in the determination of declinations with a fair degree of success, because, to a large extent, each observer's work in a period of twelve or twenty-four hours is independent of that of his fellow's; but even this work is better when done by one skilled observer alone. Fundamental right ascensions, however, cannot be determined with the requisite accuracy, and the necessary freedom from systematic errors, if more than one or, at most, two observers work with the same instrument. If only accidental errors of observation, or such as are due to atmospheric disturbances, uncomfortable positions, or the unsteady nerves of the observer, were introduced by increasing the number of observers, then increasing the number of observations would tend to diminish the error of the result. But the personal errors of observers, and their various habits of manipulation, are of the same nature as systematic errors, and cannot be eliminated by increasing the list of observers or the number of observations.

Of the many valuable star catalogues in existence, I know of none in which the right ascensions depend upon the observations of more than one astronomer, where it is possible to know, or to eliminate, either the constant or the variable errors due to the personal equation of the observers.

In the current astronomical work of this country in which we, as members of this section, are especially interested, observations and discussions, planned solely, and properly carried out, for the determination of absolute star places, are quite unknown. The necessary instrumental outfit, with the exception in some cases of a clock of the requisite quality, exists in several observatories, and I have no doubt that trained observers of the highest character can be found to meet all demands.

With the exception of a few Government establishments, and of those built to promote a higher grade of instruction, the observatories throughout the world have been founded generally for some special purpose. Their existence depended upon some endowment or bequest originating in the real or fancied interest which the wealthy benefactor took in some popular branch of the science, and this founder, with a real enthusiasm for the stimulation of research, and a noble generosity that deserved recognition in a broader field, often unwittingly limited the scope of his foundation and restrained the usefulness of his gift. Utility or novelty, separately or in combination, were frequently the groundwork on which were based the successful claims for pecuniary assistance in founding and maintaining astronomical observatories. The working observatories founded fifty years or more ago, with scarcely an exception, were supported entirely in the belief that the results of the observations would be, directly or indirectly, beneficial to navigation and to commerce. At that time this belief rested upon a reasonable basis. This plea for the construction and support of observatories is sometimes heard even at this period in the evolution of science, in spite of the fact that, if every fixed observatory in the world were destroyed to-day, no interest of navigation or commerce would suffer for the next fifty years. The function of astronomy in promoting the development of navigation and in fostering the extension of commerce has been completed.

In the periodical struggle with wealthy patrons to secure the yearly stipend, and with corporations and legislative bodies to obtain the annual appropriations for the support of observatories, may be found perhaps an apparent, if not a sufficient, motive for selecting the class of work that is pursued in most of the American observatories at this time. The apparent conclusion of those who have sought financial support for astronomical observatories seems to have been that such aid could not be secured except for some special work or research, and that the particular branch of investigation selected must be one that promised either immediate and novel results, or such as would enable capital to win, either in material benefits or in popular reputation, some returns for the risks incurred in speculative advances. Persistence in these theories and in the consequent lines of action, has doubtless resulted in the evolution of a certain type of astronomer, and also of a corresponding type of astronomical patron, whether the latter be an individual, a corporation, or the legislative agents of millions of intelligent people. Such a result would be the obvious outcome of the forces in action.

The motives that actuate the early settlers in new countries, that guide them in the struggle with the untamed forces of nature, arise mainly from the material interests of the pioneer. As the subjugation of the land progresses and the comforts and luxuries of life are substituted for the bare necessities of existence, the higher, intellectual side of humanity asserts itself and demands, not only a hearing in the councils, but also its share in the advantages won in the campaign for material prosperity.

The progress in the development of the various stages of civilization has its parallel in the evolution of the science of modern astronomy. For many centuries the timid navigator skirted the familiar shores of his native land, or, occasionally lured by the hope of unusual gains, he rashly tempted fate by adventurous cruises along distant shores that bore no name in the traditions of his forefathers. But, however lofty his ambition, he never allowed the known or unknown peaks and headlands to sink below his horizon. To him the open ocean was a symbol of infinite space that he dared not explore until astronomy furnished the key to its uttermost recesses, and the art of navigation rose to the dignity of a science.

Greenwich Observatory was founded in 1675 to promote the interests of navigation. The royal warrant appointing the first astronomer royal also declares that his duty is "forthwith to apply himself with the most exact care and diligence to the rectifying the tables of the motions of the heavens and the places of the fixed stars, so as to find out the so much desired longitude of places for the perfecting the art of navigation." Right faithfully have the successive astronomers royal carried out the spirit of the royal mandate. For many years the success was far from uniform, nor was the progress always satisfactory, but, through adversity as well as prosperity, the original design of the foundation was always kept in view, and the results have been commensurate with the effort. If the work of all the other observatories of the world were neglected or destroyed, the data in the annual volumes of the Greenwich Observatory would be sufficient, not only to build anew the science of navigation, but to reconstruct the entire planetary and lunar theories. Surely there can be no more flattering commentary on the value of a well-planned system of observatory work closely followed, through two centuries, with true Anglo-Saxon pertinacity.

The history of Greenwich Observatory is in many respects that of nearly all the observatories, of that early epoch, that have survived to the present time, but most of the urgent needs that led to their foundation have ceased to exist, and new problems have arisen to take their place. The immediate material and commercial advantages, sought for in obedience to the demands of the original foundations, have been fully gained, and the scientific results obtained from the same researches remain a permanent benefaction to the whole world.

To this extent the science of astronomy is deprived of some, perhaps the most efficient, of the influences that commended it to public approval and support during the last two centuries; and the science has now reached a period in its development where we may with propriety consider two pertinent questions. First, what has astronomy gained for itself in the effort to present, in its results, commercial advantages or popular reputation to its patrons, in return for financial support?

Second, what shall be its future attitude when seeking aid in the foundation and endowment of new observatories or in the maintenance of those already in existence?

It may be assumed without fear of contradiction that after the revival of astronomical studies in Europe the rapid development of practical and applied astronomy and the consequent establishment of a large number of observatories was due to the stimulus derived from newly-awakened interests of navigation and commerce. Around these centres of scientific activity the astronomers of the world gathered to discuss not only the problems of practical astronomy, but the more abstruse, theoretical questions which lay at the foundation of the higher branches of the science. The work of each observatory not only furnished the means for determining the accuracy of the numerous theories then extant, but it produced original data on which new theories were constructed, to be in their turn subjected to the rigid test of observation. In the extreme interest evolved in such discussions by those who eagerly sought the key to Nature's methods in the simple form of general laws, the minor problems of practical astronomy were soon solved or passed over to clear the way for the more profound questions that involved the motions in the solar system and the structure of the stellar universe. So, indirectly at first, with a zeal superior to all obstacles, and an ambition that looked beyond the simple and practical idea underlying the original foundation, astronomers have steadily but persistently sought for Nature's general laws in the labyrinth of complex phenomena, have devoted years of intense labour to the most refined tests of methods and theories, and finally, have won for their exacting but fascinating study the foremost place among the sciences. Success in all these labours has justified the wisdom of those royal and wealthy patrons who generously gave their support when a favourable issue was by no means certain.

In its practical results astronomy has returned to mankind a thousand-fold the cost of founding and maintaining its observatories, and at the same time it has developed a science whose field of action includes not only the figure, motions, and positions of our own insignificant planet, but it reaches the uttermost limits of the universe.

If the second question be regarded as involving only a simple problem in ethics it could be readily answered by following the homely, but sometimes pertinent, injunction to "speak the truth." But in view of the complexity of interests now existing this question has a wider signification and deserves some consideration. As already stated, utility or commercial advantage can no longer be given as a reason for carrying on astronomical investigations. Novelty, combined with a desire for architectural display and an absurd ambition to secure the largest telescope and the greatest variety of astronomical instruments, has, even at the present time, a place, and sometimes a prominent one, among the reasons assigned for establishing new observatories. In view of these facts, it is surely the duty of astronomers to see to it that, for their own reputation and for the present and the ultimate welfare of their science, the true purpose of astronomical study and research, and the grounds for the existence and the support of observatories should be frankly given and courageously maintained. It is possible that pecuniary profit may sometimes indirectly arise from some branches of astronomical work or investigation; but the only sound and honest reason that can be given for such work is, that it stimulates the highest form of intellectual activity, widens the already broad field of investigation, and increases the sum of human knowledge. Whoever pleads the cause of astronomy on a lower plane discounts the intelligence of himself or of his audience. Why should the astronomer stoop to select a less noble theme, or consider it from a lower point of view? He who leads an intelligent and thoughtful life must feel himself in daily touch with those phenomena that are involved in the most important astronomical problems of the present and the immediate future. The figure and motions of the earth which he treads; the constitution and translation of the sun that invigorates his life and lights his days; the movements and structure of the moon and planets that beautify his nights; the proper motions and distances of the countless stars that nightly set before his eyes the highest types of rigorous law and of boundless space that the mind can grasp; all of these, and more, tend to convince him that the constantly growing demand for broader and more exact knowledge is ample warrant for the time and expense involved in the most profound astronomical investigation. In this direction lies the justification of astronomical research; on this basis the astronomer is sure of the stimulating support of every cultivated mind as long as the questions "why" and "how" are constantly reiterated and still are unanswered. On this ground, and on this alone, rest the valid reasons for the expenditure of corporate, municipal, or national funds for the establishment of expensive observatories and the prosecution of astronomical investigations; and in the closing years of this century the conscientious astronomer can in no way more thoroughly vindicate the highest claims of his science than by holding the standard of work well above the popular fancies of the hour, and by devoting his time and energy to that class of fundamental work that shall not only satisfy the rigorous demands of the present time, but shall make the last decade of the nineteenth century an important epoch in the real progress of astronomy.

GEOLOGY AT THE BRITISH ASSOCIATION.

NEARLY fifty papers were contributed to Section C during the meeting of the British Association, and although no new facts or theories of startling interest were brought forward, the record of the year's geological work was decidedly above the average. Owing to Professor Lapworth's regrettable illness his address could not be delivered until Monday, and the chair at the meetings had usually to be taken by one of the vice-presidents.

Glacial and local papers occupied the first two days, the most remarkable being the pair by Messrs. Peach and Horne on the Radiolarian Chert of Arenig age, once probably a deep-sea ooze, which covers 3000 square miles in the southern uplands, and passes like the Moffat shales into sediment when traced towards the north. When the chert is traced to within half a mile of the Loch Doon granite the quartz has become quite granulitic, the radiolaria being still recognizable in the matrix although there is a faint development of mica; close to the granite the rock is completely recrystallized, and consists entirely of large quartz particles full of liquid cavities and rounded inclusions of biotite. Dr. Hicks claimed as pre-Cambrian some tender gneisses, schists, quartzites, and limestones, of the central Highlands, of which he gave microscopic descriptions, and Prof. Blake argued that the discovery of *Olenellus* of the type of *O. Thompsoni*, in beds above the Torridon sandstone, did not necessarily parallel these beds with those containing *Olenellus* beneath the Paradonides zone of America. Amongst the other papers dealing with Palæozoic rocks may be noted Prof. Blake's discovery of a felsite like that of Llyn Padarn, apparently intrusive into the Llanberis slates, seen in a new section in the Penrhyn quarries; Prof. Sollas's discovery of bodies like radiolaria in the slates of Howth, and the limestone of Culdaff; and Prof. Bonney's comparison of the pebbles of the English Bunter with those in the old red conglomerates in Scotland.

Several important glacial papers were read. Dr. Crosskey reported on the recording of new erratics chiefly in the north of England. Mr. Lomas traced Boulders of the Ailsa Craig, Riebeckite Rock, on Moel Tryfaen, in Anglesey and the Vale of Clwyd, at Liverpool and Birkenhead. Mr. Bell considered that the evidence from the shell-beds of Clava and Chapelhall was less consistent with the theory of submergence than with that of transportation by land ice. Messrs. Peach and Horne adduced evidence to show that in Sutherland and Ross-shire, at the time of greatest glaciation, the ice-shed was to the east of the present watershed, and the lofty mountains of Assynt and Loch Maree were glaciated by ice travelling westward. Mr. Clement Reid gave a list of twenty-eight species of Arctic plants from a series of silted-up tarns at Corstorphine and Hailes, near Edinburgh. Prof. Axel Blyth exhibited and described a beautiful set of plant remains preserved in calcareous tufas from Gudbrandsdal, in central Norway. The investigation of the Elbolton cave will probably be completed this year, and it has so far failed to reveal any trace of occupation by Palæolithic man. Messrs. Peach and Horne have studied one out of a group of caves in the Assynt limestone of Sutherlandshire, and found charcoal with split and calcined bones of reindeer, fox, and grouse in the upper layers, and a finely preserved canine tooth of brown bear at a depth of about five feet from the surface. Mr. Coates gave a description of the cuttings, chiefly in boulder-clay, in the Crieff and Comrie railway. And Mr. Kendall attributed the glacical period to variability in the heat of the sun.

Foremost amongst the palæontological papers stands that of Mr. E. T. Newton, in which was given an account of several remarkable skulls obtained from the Elgin sandstone and probably belonging to two or three species related to the African dicynodonts; together with these occurred the skull of a reptile allied to Pareiasaurus of the Karoo beds, but with no less than thirty horns varying from a quarter of an inch to three inches in length. Mr. M. Laurie described two new species of *Eurypterus*, two of *Stylonurus*, and one of a new genus, *Drepanopterus*, of Eurypterids from the Silurian rocks of the Pentland Hills. The work of the type committee still continues, and lists have been received from several museums and private collectors. Reports were also presented on Cretaceous Polyzoa and Palæozoic Phyllopoda, and a paper by Mr. Bullen Newton recorded the discovery of *Chonetes Pratti* in the carboniferous rocks of Western Australia.

The petrological papers included a note on the Malvern crystalline rocks, by Mr. Irving; one on the felsites, andesites, and diabases of Builth, by Mr. Woods; and a short note on the Limerick Traps, by Mr. Watts. Mr. Ussher endeavoured to prove that there must have been a rigid mass occupying the position of the Devon and Cornwall granites at the time when the stratified rocks were folded, in order to account for the deviations in their strike. Mr. Goodchild argued that the junction of the granite of the Ross of Mull was best explained by the absorption of sedimentary rocks in the granite. Mr. Harker explained the presence of porphyritic quartz in basic igneous rocks by supposing that it had formed in the upper layers of a magma basin, and sunk to its present position by gravity. Mr. Teall gave a sketch of the succession of rocks in an area of gneisses, which accorded with the succession from basic to acid types in plutonic masses; and Mr. Somervail endeavoured to explain the chief rocks in the Lizard area by segregation from a single magma.

Finally must be mentioned Professor Hull's paper on the Physical Geology of Arabia Petrœa; a very interesting paper by Miss Ogilvie, on the landslips in the South Tyrol, in which she showed how much the mapping of that region was complicated by the constant repetition of portions of the strata by landslips; a new classification of the New Red Sandstone of Northern England, by Mr. Goodchild; and papers on the Green sand and Fuller's Earth of Bedfordshire, by Mr. Cameron.

Dr. Johnstone Lavis's report on Vesuvius chronicled the phases of eruption in the past year, and was illustrated by a beautiful series of photographs, chiefly of fumarolles and spiracles in the streams of lava. Mr. De Rance's report on underground water was continued. Mr. Davison's earthquake report dealt chiefly with new forms of seismic apparatus, and the photographic committee recorded that the collection of geological photographs now numbered 700, amongst which half the English counties and Scotland were, however, poorly represented. An excellent exhibition of the photographs was held in a room provided for the purpose, where also the Geological Survey of Scotland showed a fine series of views illustrating the scenery and structures of the ancient gneisses and schists of the Highlands.

MECHANICS AT THE BRITISH ASSOCIATION.

SECTION G had a good meeting at Edinburgh this year, there being a great improvement on last year's gathering at Cardiff. On the members assembling on Thursday morning the fourth inst. in the old University Buildings the first business was naturally the Presidential address. Prof. W. C. Unwin, F.R.S., who this year occupied the chair, is eminently fitted to preside over the Mechanical Science Section. His knowledge of the scientific side of mechanics is well known, and his past experience in the region of practical mechanics puts him thoroughly in touch with the many engineers who frequent the section. His address, which we have already printed, was listened to by a large audience, the theatre being quite full. The vote of thanks to the President for his address was moved by Lord Kelvin and seconded by Mr. Deacon, of Liverpool.

The first paper on the list was a contribution from Mr. James Dredge and Mr. Robert S. McCormick on the American Exhibition, which is to be held next year in Chicago. The paper gave a good general description of the coming show from the engineer's point of view; but the subject is one that offers better scope for the members of Section F. It is manifestly impossible to give anything like a good engineering description within the limits of a short paper, whilst the advantages and disadvantages of exhibiting might well have supplied a theme for discussion in the Economic Section. In fact, the discussion which followed the reading of the paper turned wholly on this branch of the subject. The next three papers were of a sanitary nature. Prof. George Forbes and Mr. G. Watson, of Leeds, both dealt in the disposal of town refuse, the former bringing in the electrical lighting of Edinburgh as a part of his scheme. Mr. Forbes points out that in the electric lighting of towns the demand for power is but for a few hours daily. With no system of accumulators, or power storage, this necessitates a large plant compared to that which would suffice if the demand could be made continuous. The author, therefore, proposes to use Arthur's Seat as an accumulator, by forming a reservoir on its summit, and into this reservoir water would be pumped continuously. The head of water thus obtained would be used for working turbines, which would be of sufficient power for the maximum demand. There would thus be a gain through keeping the steam engines constantly at work, smaller engines could be used, and there would not be the loss incidental to raising steam or keeping the boiler fires banked. The great feature of the scheme, however, is to use the dust-bin refuse of the city as fuel for raising steam. The author would erect destructors, and the waste heat from these would be passed through the boiler flues. Prof. Forbes quoted figures in support of his contention that the scheme is practicable, and he instanced what has been done at Southampton, and elsewhere, in the matter of using domestic refuse for steam-generating purposes. We are not able to criticise the details put forward, but we may venture to say that, if the scheme can be worked out practically, engineers will have put before them an example of the use of waste material which many have not hitherto considered capable of being so successfully applied. The author stated that the refuse of a city, if properly burnt, would generally supply sufficient heat to raise the steam necessary for the electric lighting required. That is a very satisfactory adjustment of supply and demand, and if Prof. Forbes can show municipal engineers how to put it in practice he will have rendered a most important service for which every one should be devoutly grateful. After disposing of the particular scheme for the refuse destruction and electric lighting of Edinburgh, the author gave some interesting particulars of that which has already been done in this country in the matter of burning town refuse.

The next paper was contributed by Mr. G. Watson, of Leeds, and was an excellent treatise on the refuse-destructor question. The various types of apparatus which have already been put in use were illustrated by wall-diagrams, and the chief points in their construction were explained. Mr. Watson is of opinion, and he supported his opinion by results of actual experience, not only that dust-bin refuse can be burned in a properly constructed destructor without nuisance, but that the waste heat can be used for raising steam; or, if required, that dust-bin refuse and sewage sludge, containing 90 per cent. of moisture, may be satisfactorily burnt together, the Horsfall destructor being, apparently, particularly suitable for the purpose. The whole subject is one of great and growing importance. It is to be regretted that both these papers were not printed and distributed previously, so that a thorough criticism of the various points raised might have been made during the discussion.

A paper by Mr. R. F. Grantham, on the absortpion and filteration of sewage was next read. The author gave accounts of many examples that have been carried out in different parts of the world, and of experiments made in this connection. Mr. Grantham is of opinion that the Maplin and Foulness Sands at the mouth of the Thames might be used to advantage for treatment of the sewage of London.

The next paper was of a different character. It was by Mr. G. F. Deacon, and contained a description of the work the author had carried out in shield tunneling in loose ground whilst constructing the Vyrnwy Aqueduct tunnel under the Mersey. The work, as is generally known, was one of remarkable difficulty, and the manner in which the various obstacles to its completion were overcome affords a valuable lesson for engineers.

Mr. D. A. Stevenson next read a paper in which he advocated the construction of a ship canal between the Forth and the Clyde. The scheme included a tunnel high enough to pass the masts of big vessels, and locks sufficiently large to take in ocean-going steamers. The estimated cost is £8,000,000. After a short discussion of this paper the section adjourned.

On the next day, Friday, the 5th inst., the first business was the reading of a paper by Mr. D. Cunningham, in which he described a mechanical system for the distribution of parcels. The device was illustrated by means of a working model, without the aid of which, or drawings of the mechanism, it would be difficult to make the principle understood.

Mr. Alexander Siemens next described two electric locomotives which his firm had recently supplied to the City and South London Railway. These, as it is proper they should, have been more successful in their working than the engines originally placed on the line. The armatures of the motors are wound on the axles, so that no gearing is required. According to diagrams displayed, the efficiency varied between about 90 and 94 per cent. Each locomotive, fully equipped, weighs 13½ tons, and the weight of the train of carriages is about 21 tons, without passengers. The weight, we believe, is considerably greater than in the original locomotives used on the line, and this is undoubtedly an advantage. Mr. J. H. Greathead, Professors Silvanus Thompson, and G. Forbes took part in the discussion; in replying to which the author attributed the success of the motors to large armatures and large field magnets. Prof. Silvanus Thompson stated that Messrs. Mather and Platt, of Manchester, are now building an electric locomotive which is to be more powerful than anything that has gone before.

Hydraulics next occupied the attention of the section, Messrs. F. Purdon and H. E. Walters describing an interesting tide-motor which they have devised and constructed. The machine takes the form of a floating barge or flat, which is moored athwart the tide-way. There are two drums placed some distance apart, and on these drums a chain is made to travel by floats attached to it, which floats project downwards into the water, and are carried along on the forward stroke by the action of the tide, whilst the return stroke is made in the air. As the flat is moored athwart the stream—in order to utilize the greatest possible area of the current—and as the chain travels fore and aft, guides are used to conduct the water in the proper direction to actuate the floats or paddles. The guides also concentrate the stream. These are roughly the fundamental features of the design, further details of which we are unable to give through limits of space. The machine, however, is very interesting, and is perhaps one of the most promising and best worked-out motors of its kind. There appears now to be better prospect for inventions of this nature than heretofore, on account of the facilities offered for transport of power by means of electricity. It is always a tempting problem to try to use some of the vast store of energy running to waste in the tides, although the question is one beset with practical difficulties that have been sufficient hitherto to make tide-motors very scarce.

A paper by Mr. Pearsall, in which he described a new arrangement of hydraulic ram, which he had made, was next read; Prof. Blyth described a new form of windmill on the principle of the Robinson cup anemometer; and Mr. G. R. Redgrove having read a contribution on Levavasseur's flexible metallic tubing, the second day's proceedings were brought to a close.

The next sitting was held on the following Monday, the section not meeting on Saturday. The arrangement was decidedly a pleasant innovation, the Saturday morning's meeting being by no means popular. Whether there be few or many papers, it seems impossible to get through a sitting in a short time, as there are always one or two speakers, at any rate, who will spin the discussions out, so that those who are obliged to stay to the end have no time to get lunch before starting on the excursions. Section G made a trip to Glasgow on the Saturday, and were rewarded by perhaps the finest exhibition of marine machinery ever collected in a single installation. This comprised the propelling engines of one of the pair of enormous vessels the Fairfield Company are building for the Cunard line. The engines were erected in the shop, and one was enabled to get a fair prospective of their grand proportions, such as will be impossible when they are confined to their natural position on shipboard.

On the section again assembling on the Monday following the first business was the reading of the report of the committee appointed to consider "The Development of Graphic Methods in Mechanical Science." This report had been prepared by Prof. Hele-Shaw, of Liverpool, who must have spent a vast amount of pains in compiling the very bulky document, which was read in abstract. The bibliography should be especially valuable. This is the second report that has been presented by the committee, and, we believe, the subject is to be further investigated. The use of graphic methods is far less common with engineers than it might be with advantage, and the matter is one which the Mechanical Section of the British Association is especially fitted to deal.

Mr. Preece next read two papers, in the first of which he took the municipal authorities to task for causing stack pipes to be disconnected from the drains, and thus depriving these natural lightning-conductors of their lead to earth. If Mr. Preece's prognostications are fulfilled there will be a great increase in casualties from lightning when the new legislation comes widely into effect, unless some other means be taken to make connection between stack pipes and earth. Mr. Preece did not read his second paper, but contented himself with saying a few words to signify its scope. Its title was "The use of secondary batteries in telegraphy." For the past seven years secondary batteries have been used at the Post Office to supply current to two large groups of circuits, one group consisting of 110 single needles, and the other of 100 Morse inkers and sounders.

Mr. Gisbert Kapp next read a practical and interesting paper on "Power Transmission by Alternating Current," describing an installation which has been carried out at Cassel. In that town the water supply is a municipal undertaking, the source being at a distanee of four miles or so from the town. In the summer a large quantity of water is used, and for this reason a certain amount of pumping has to be done. The pumps are worked by turbines. In the winter the existing natural gravitation supply is sufficient, and the turbine pumps are, therefore, not required. It is, of course, in winter that the chief demand for light occurs and then the turbines, in place of being idle, are used for driving dynamos. Mr. Kapp explained by means of diagrams the manner in which a storage system is carried out so that the turbines may be kept constantly at work. The power is transmitted by a single phase alternating current from the generating station to two sub-stations at Cassel. At one of the sub-stations there is a battery which is charged during the hours of light load, to be in turn drawn upon during the time of heavy load. Each of the two sub-stations contains a transformer so that the distribution is by continuous current, whilst between the generating station and the sub-stations the current is alternating, the pressure being 2000 volts. The installation was the work of Mr. Oskar von Millar, Mr. Kapp designing the alternators. The author gave a good many details of the arrangement of which the above is an outline. In the discussion which followed an interesting point was raised as to the effect of putting the alternators out of step. The author said that in the present instance he had no hesitation in putting the load on suddenly and no effect followed, but if the load were suddenly taken off, the machine would start howling in a frightful manner until it again got in synchrony. This was alarming at first, but not otherwise hurtful.

Mr. E. H. Woods next read a paper in which he gave particulars of a new design of electric locomotive. The driving wheels are placed horizontally, the necessary grip being, we understood, obtained by springs, which press the pairs of wheels against a central rail. There is an ingenious device for points and crossings which was illustrated by a model. The motor is to be kept running continuously, the grip of the wheels being released when the train is stopped, the power then be absorbed by frictional brakes. The relative value of this device naturally depends on the length of the stoppage. Mr. Kapp and Prof. Forbes both spoke on the question of continuous running motors, neither appearing to look with favour on the device.

Monday is generally devoted wholly to electrical engineering, but on this occasion the papers on the subject were not sufficiently numerous to fill up the sitting. The rest of the day was, therefore, filled up with papers of a miscellaneous nature. The first of these was a contribution by Lieut. W. B. Basset, R.N., who described a very ingenious coin-counting machine which has been recently placed in the Royal Mint. It would be impossible to describe this apparatus without the aid of drawings; but it may be stated that 3,000 coins can be counted in a minute, or one ton in three-quarters of an hour. The coins are made to move along a channel of such a size that only one can pass at a time. They are forced along by means of two driving wheels, actuated by an electric motor. At the lower end of the channel is a wheel with notches in its rim, the notches being of a shape that the coins just fit into them. The wheel is made to turn by the coins as they are forced forward, the action being comparable to that of a rack and pinion, the rack being formed by the procession of coins pushed forward by the driving wheels. The counting wheel must necessarily pass a coin for each notch or tooth it advances, and as a given number of teeth always go to a revolution, an accurate record is obtained. The machine in the Mint is arranged to count pence, half-pence, piastres, half-piastres, and Hong Kong cents. It counts on an average over two million coins a month without error.

Mr. Killingworth Hedges next read a paper on "Anti-Friction Material for Bearings used without Lubrication." This referred chiefly to a bearing composed of finely-powdered carbon mixed with steatite, which the author had found valuable. He referred to the advantages of non-lubricated bearings, such as saving in labour, cost of oil, and cleanliness. In the discussion which followed, Professor Unwin well summed up the question by saying that though there might be a higher co-efficient of friction with a non-lubricated bearing, manufacturers could generally well afford a small additional expenditure of power in order to be free from the defects of oiled bearings.

A paper by Mr. B. H. Thwaite on high-pressure boilers, which does not call for notice here, was the last read on this day.

The last day on which Section G sat was Tuesday, the 9th inst., when the proceedings were opened by a paper by Mr. D. A. Stevenson, entitled "Petroleum Engines for Fog Signalling," being read. The paper, which was read by Mr. C. A. Stevenson in his brother's absence, stated that the maximum number of hours of duration of fog in Scotland was 395 per annum. For sounding the siren various motors are available, which may be actuated by the waves or tides, manual labour, clockwork, steam, hot air, gas, or oil. The author states that the oil engine is the best for the purpose. He states, however, that all fog signals which appeal to the ear must be of an unreliable nature, and he would prefer some method, such as had been proposed by Mr. C. A. Stevenson, in which an electric conductor is laid down off a coast, so as to act on an instrument attached to each vessel. It would have added to the value of the paper had sufficient detail of this device been given to afford the meeting an idea of its general principle. As the description stands we quite fail to see how a useful result could be brought about. An interesting discussion followed the reading of this paper, in which the chief feature was the speech of Mr. A. R. Sennett, who pointed out that water is a better medium than air for conveying sound, and reminded the meeting that sound was very liable to be deflected by "acoustic clouds." Tyndall found that the presence of such clouds reduced by one-third the distance at which a given sound could be otherwise heard. Mr. David Cunningham, the harbour engineer at Dundee, gave a remarkable example of the influence of acoustic clouds. He had gone out in a steam yacht when the siren was in operation. At a distance from it of half a mile the sound was not to be heard, but when they had steamed four miles the siren was again audible. It had been sounding the whole time. To return to Mr. Sennett's remarks, that speaker said he proposed taking advantage of the sound-carrying power of water in the following way. He would have the siren, which indicated a danger, submerged in place of being in the air. It would be arranged to give off a certain note. In each ship there would be a chamber to which the sea would have access, and in this would be a diaphragm which would be tuned to the same note as that emitted by the siren. By the well-known law the diaphragm would not resound unless the note to which it might be attuned were in harmony with that given off by the siren, and therefore false alarms would not be given by the sounds produced by paddle wheels or in other ways. An officer would be placed in a padded cabin, so as to isolate him from the noises of the ship, and by means of an ordinary speaking-tube he would be able to hear the vibrations of the diaphragm, which, as stated, would only take place when they synchronised with the sound-waves produced by the siren. Mr. Sennett's proposal is ingenious, and may contain the germ of a principle of great value. We understood him to say that he had made some experiments in this direction, and that these had been encouraging. It is obvious, however, that investigations of this nature must be somewhat costly, and can lead to but little prospect of pecuniary reward. We would suggest that the matter is one that might well be taken up by the Board of Trade or the Trinity House. Perhaps some of those big shipowners who do their own insurance might be induced to give assistance in this direction. It is quite possible, and indeed probable, that we have been entirely on the wrong tack in sending sound-signals through the air. The experience of Prof. Hughes, quoted by Mr. Sennett, when he found the sound of two stones being knocked together under water could be heard for a distance of half a mile, and heard so distinctly that the Professor did not wish to repeat the experiment, bears on this point. An ordinary bell has been struck under water, and the sound conveyed a distance of nine miles.

Mr. C. A. Stevenson next read a paper of his own "On the Progress of the Dioptric Lens as used in Lighthouse Illumination." This paper was largely historical, going back to the early days of the century, when Alan Stevenson introduced the Fresnel apparatus in Great Britain, and bringing the record up to the year 1886, when the author proposed the spherical lens, an example of which was introduced in one of the Fair Isle lighthouses. This introduction of the spherical refractor has made practicable the construction of more powerful apparatus, with less total space occupied. It has also rendered practicable a quadrilateral arrangement with hyper-radiant lenses. This arrangement has been installed at Fair Isle, the lenses being cut so as to give two flashes from each side of the quadrilateral. An experimental example for Ireland is 2 m. focal distance, and the spherical refractor is 7′ 6″ in diameter, and will give one flash from each side of the quadrilateral.

Mr. A. R. Sennett next read a paper which was both interesting and of practical importance. Its theme was the much ill-treated smoke-prevention question, and we may at once say it was refreshing to find this important but ever-abused problem approached in an intelligent manner. Mr. Sennett has evolved a very simple device which, it might perhaps be rash to say, has exorcised the smoke fiend in regard to boiler furnaces; but if we are to accept his statements—and we see no reason why we should not—there is no longer excuse for steam users allowing smoke to emerge from boiler chimneys. We all know it is not difficult to prevent smoke if fuel economy be left out of the question, but Mr. Sennett tells us he not only prevents smoke, but saves coal. The latter part of the claim is vouched for by Professor Alexander Kennedy, who is perhaps our best authority on this subject; and, with regard to the smoke prevention, Section G was able to judge for itself, as the author had a fair-sized return-tube boiler at work in a yard close to the meeting-room. The paper was of considerable length, but was listened to with interest throughout. By means of wall diagrams, devices of various classes, previously introduced, were illustrated and described. These played much the same part as the awful example at a teetotal lecture, only serving to emphasize the virtues of the author's own invention. Some of them, it must be confessed, were sufficiently absurd; one especially, in which the products of combustion were cleansed from soot by a sand filter, afforded the meeting a good deal of amusement. We imagine the impression of the average engineer to be that the drier and hotter the air fed to a furnace the quicker and more perfect would be the combustion. This Mr. Sennett shows to be not exactly the fact, or, at any rate, that the presence of steam with the air promotes combustion. He says that hydrogen, steam, or aqueous vapour, in the furnace is necessary. He combats the view, "too readily assumed," that the presence of an excess of oxygen contained in dry air will of necessity effect complete combustion. The advantage of supplying air above the grate bars, as well as below, is, of course, well understood, and it is with the volume of air introduced above that the author chiefly deals. His device consists chiefly of an air injector, the steam for inducing the air-current being super-heated in a coil placed in the chimney. The apparatus is termed a transformer, because it transforms the kinetic energy of a small current of steam at high pressure into that of a large current of air at low pressure: a description which conveys the whole scheme of the invention, although the working out of the details requires some attention. With the transformer Mr. Sennett has carried out some experiments. He worked it firstly by steam, and secondly by compressed air, and he found that the volume of air required for combustion was very much less in the former case than in the latter. In explanation, or rather in illustration, of this fact the author quotes several interesting facts. Mr. H. Brereton Baker investigated the phenomena which accompany the burning of carbon and phosphorus in oxygen. Finely powdered charcoal was carefully dried and sealed up in a hard glass tube containing oxygen saturated with water. The tubes were placed in a flame, and the carbon burnt with bright scintillating flashes. When the oxygen was dry no combustion took place in the tube, though the latter was heated to bright red; a result which came clearly as a surprise to many of the members of non-chemical Section G. Mr. Baker has said that the results obtained clearly show that the burning of carbon is much retarded by drying the oxygen. With regard to the presence of moisture and the behaviour of carbonic oxide gas in oxygen the effect is even more remarkable. The author quotes Prof. H. B. Dixon, who says: "That if the mixture of the two gases be very carefully dried it is no longer explosive, and a platinum wire may be heated to redness in it without causing explosion; oxidation of the carbon monoxide to dioxide then taking place gradually, and only in the immediate neighbourhood (at the surface) of the glowing wire. A burning jet of carbonic oxide may even be extinguished by plunging it into a jar containing dried oxygen." We will quote one more interesting fact in connection with this subject. Sir Lowthian Bell has noticed that the gases at the throat of blast furnaces, which are of a temperature of about 250 to 300 Cent., are not inflammable in atmospheric air. Any small quantity which escapes does so without undergoing combustion. But the moment a tuyere commences to leak the gas takes fire; just as a small quantity of hydrogen in the eudiometric researches produced explosion in a mixture not previously influenced by the electric spark. The author does not attempt to decide whether the acceleration or retardation of the union of oxygen with the evolved hydro-carbon gases is due to the presence of aqueous vapour or of the hydrogen. Section G may fairly look to Sections A or B for enlightenment upon that point.

We have given so much space to what we think the most interesting part of Mr. Sennett's paper that we may, perhaps, be doing him the injustice of suggesting that other points do not receive attention. This, however, is not the case, for he does not lose sight of the leading canons of furnace practice, such as proper admixture of the gases, adequate space for combustion, keeping the gases from contact with the heating surface (from this point of view the cooling surface) of the boiler, and other matters, of a similar nature. The result of the whole arrangement is that smoke is undoubtedly prevented from issuing from the funnel. In the boiler referred to a very dirty coal was burned, the result being a particularly pungent smoke, which was sometimes carried down among the spectators by an eddying wind. When the transformer was put in operation this smoke entirely disappeared. Upon the apparatus being put out of action the sable cloud was again to be seen rolling forth from the chimney-top. These operations were repeated several times, the fire being constantly supplied with green fuel, so as to keep it in its smokiest condition.

Following Mr. Sennett's paper a contribution on the same subject was read by Colonel E. Dulier. The author of this paper deals with the domestic fire, to which, of course, the greater part of the smoke of civilization is to be attributed, but he does not aim at the prevention of smoke, but simply to its arrestation before its gets into the air. In order to effect this object he proposes to wash the chimney gases with a spray, and thus precipitate all soot. He also claims to arrest the greater part of the sulphurous acid, which is of even greater importance. Every dweller in towns and cities will wish Colonel Dulier well in his enterprise, but there are some very big difficulties in his way. The biggest perhaps is that before the plan can become general legislation must be brought to bear. Unhappily dwellers in towns and cities are so little disinterested that the average householder would prefer to see his next-door neighbour erect a costly apparatus (the first cost for a seventeen-chimney house is said to be about £50) rather than go to the expense himself. The large quantity of water required for a general smoke-washing would be a serious problem, not only of cost but of supply at any price, although it is quite possible this difficulty could be, as it should be, met. The cleaning out of the apparatus would be also a serious matter, for the tarry deposit due to smoke-washing is of a particularly tenaceous nature.

The sewage problem next occupied the attention of the meeting, Mr. Crawford Barlow reading a paper on "The London Sewage Question." Mr. J. Cooper also read a paper on "The Sanitation of Edinburgh." The last paper read at this meeting in this section was contributed by Mr. H. C. Carver. It related to fire extinction on board ship. The author has devised an apparatus by means of which he can turn the effluent gases from the boiler furnaces into the hold of a ship where fire is raging; the gases having been previously washed and cooled. The apparatus has been tried practically, and has been found to answer remarkably well. The ordinary practice is to turn boiler steam into a ship's hold; but the spent gases from the furnace are naturally more effective, as steam condenses, and air is thus drawn in. Nevertheless, steam is better than nothing.

After the usual votes of thanks the business of the section was brought to a close.

ANTHROPOLOGY AT THE BRITISH ASSOCIATION.

After the President's address, on Thursday, August 4, Mr. E. W. Brabrook read a paper on the Organization of Local Anthropological Research. The writer, as the representative of a joint committee of delegates from the Society of Antiquaries, the Folklore Society, and the Anthropological Institute, communicated a plan for an ethnographical survey of the United Kingdom, by which observations should be made simultaneously in selected localities on the ancient remains, the local customs, and the physical characters of the people. The matter is one that will not brook undue delay, as the evidence is fast slipping out of our grasp.

The Rev. Frederick Smith read a paper on the Discovery of the Common Occurrence of Palæolithic Weapons in Scotland. The author has made patient and long-continued search in modern and ancient gravel beds of existing rivers, in "Kame" deposits, and finally in certain phases of boulder clay; and he finds abundant evidence in the shape of glaciated, broken, and crushed specimens of the weapons of palæolithic man. He has collected at least 350 specimens, which he believes to be definite evidence of the long-continued sojourn of palæolithic man north of the Border.

A paper on Cyclopean Architecture in the South Pacific Islands was read; also the Reports of the Anthropometric Laboratory Committee, and of the Anthropological Notes and Queries Committee.

In the afternoon the following papers were read:—Dr. L. Manouvrier, On a Fronto-Limbic Formation of the Human Cerebrum; Prof. G. Hartwell Jones, The Indo-Europeans' Conception of a Future Life and its Bearing upon their Religions.

On Friday, Mr. J. Graham Kerr exhibited a collection of weapons, articles of clothing, and a fire drill, used by the Toba Indians of the "Gran Chaco." He accompanied the exhibition with a few explanatory remarks. The specimens had been obtained from a tribe of the Tobas on the banks of the Rio Pilcomayo. Amongst weapons the chief were bows and arrows, the former being noteworthy from their reinforcement by a back string. The arrows were of cane, with long wooden points made of cascarandá. An arrow with an iron head was also shown, the head being formed of fencing wire beaten out.

Mr. J. Montgomerie Bell exhibited a collection of flints from the North Downs of Kent, which he called "pre-palæolithic." The peculiarities of these flints is that they are not shaped into particular forms by the will and skill of the workman, as palæolithic flints are, but they are simply stones taken from the ground and used almost in the state in which they are picked up; only the edges are altered; they are chipped flints rather than shaped flints; used tools, not made tools. Mr. Bell explained the reasons which had convinced him of their authenticity; namely, that the chipping is regular and purpose-like, such as Nature is not likely to have hit upon; it is sometimes within a hollow curve, where natural agencies could not act; the edges of many unbulbed flints have far more regular marks of wear, which is the true indication of use by man, than many bulbed flakes possess, whose edges have undoubtedly been used; and lastly, there is a sequence in the types which leads into the types of the river-valley period.

Mr. J. Theodore Bent read a paper on the Present Inhabitants of Mashonaland and their Origin. The inhabitants of this country are an oppressed and impoverished race of Kaffirs, who dwell amongst the rocks and crannies of the mountains. Their recognized name—Makalanga—means "the children of the sun," and there were traces of a higher civilization amongst them. Their origin is obscure, but references to them by early Arabian writers prove beyond doubt that a similar people inhabited the country one thousand years ago. Each tribe has its totem. Their religion has a monotheistic tendency, but they sacrifice to ancestors, and sacrifice goats to ward off calamities. Their manners are courteous and refined, and their skill in music is considerable.

Prof. A. C. Haddon contributed a paper on the Value of Art in Ethnology. In order to study such an intricate subject as Decorative Art from the point of view of the Biologist it is necessary first to confine one's attention to savage art where the problems are presented in a simpler form. In taking a definite area into consideration, such as British New Guinea, one finds that there are several distinct and well-defined artistic provinces. The Torres Strait district was characterized by the prevalence of straight and angled lines to the exclusion of curved lines and the representation of animal forms, the latter being associated with totemism. In the Gulf District the human face and form is the basis of almost all their art. In the Port Moresby District decoration is in the form of panels and mainly straight and angled lines; whereas in the South Cape and Archipelago District there is a wonderful richness of design in which curved lines are abundant.

It is well known that in this latter district there has been a great mixture of race. It would appear that homogeneous peoples have a uniform style in their art, but that race mixture tends to varied artistic treatment.

Dr. J. S. Phené read a paper on the Similarity of Certain Ancient Necropoleis in the Pyrenees and in North Britain. At Luchon, a spot where the traditions of the Pyrenees were most concentrated, remarkable customs had till recently been practised. The locality abounded with interments of a peculiar kind, more or less surrounding a central mound, serpentine in form, the head of which had been cut away and a small church erected in the cavity. The walls of this antique little church are covered with votive tablets of early Christian and pagan Roman times. Almost all the features shown had been discovered by the author in Somersetshire, Bedfordshire, Argyleshire, and Peebleshire.

The following papers were read:—A Contribution to the Ethnography of Jersey, by Dr. Andrew Dunlop. Notes on the Past and Present Condition of the Natives of the Friendly Islands, or Tonga, by Mr. R. B. Leefe. Damma Island and its Natives, by Dr. F. Bassett Smith. The Reports of the Mashonaland Committee, and of the Canadian Committee were also read.

In the afternoon a discussion on Anthropometric Identification was opened by Dr. Manouvrier, who described the system of measurements introduced by M. A. Bertillon into the French Criminal Department, and showed the manner in which they were made. He said that by its means the identification of criminals was made absolutely certain. Dr. Benedikt of Vienna also bore testimony to the efficiency of M. Bertillon's system and strongly advocated its introduction into Great Britain. Dr. Garson referred to Mr. Galton's method of identification by means of finger marks.

As a result of this discussion the Council have been requested to draw the attention of her Majesty's Government to the subject.

A discussion on the subject of Criminal Anthropology was opened on Saturday by Dr. T. S. Clouston, who reviewed the work done in this and other countries, and pointed out the failure of the workers to agree on any anatomical, physiological, or psychological data for establishing a criminal type.

If inquiry established physical, hereditary, and psychological bases of criminality, the State would have to treat the criminal from a point of view entirely different from the punitive method. The essential likeness of the epileptic and the criminal brain is one of the most striking of Dr. Benedikt's observations. What were to the doctor symptoms of disease were to the policeman and the magistrate proofs of criminality. In the rich family the physician looked after the case, in the poor family the policeman and the gaoler. Yet both cases were equally phases of brain development due to hereditary weakness.

Dr. Benedikt emphasized the importance of studying criminals of different types. They must study the classes from which the criminals came, and must not confuse the poor and miserable with the criminal classes.

On Monday Sir William Turner exhibited the coiffure of a Kanaka labourer who had been employed on a sugar plantation in Queensland. The mode of dressing the hair in locks, each of which was tied round with a narrow ribbon formed of vegetable fibre, was described. 834 such locks were present in the coiffure, and it was estimated that about 120 hairs were in each lock, making in all about 100,000 hairs in the coiffure.

Prof. Struthers read a paper on the Articular Processes of the Vertebræ in the Gorilla compared with those in Man; and on Costo-vertebral variation in the Gorilla.

Mr. J. P. Mansel Weale made a communication on the probable derivation of characteristic sounds in certain languages from the noises made by animals.

Dr. Louis Robinson read a paper on the prehensile power of infants. Long-continued experiments had proved that the muscles of the hands and arms of a newly-born infant are far stronger in proportion to weight than those of most healthy adults. In many cases a newly-born child would hang and support its weight with ease for a minute, and some for thirty seconds longer. Several infants less than a week old hung for over a minute and a half, a few others a fortnight old for nearly two minutes, and one child of about three weeks old for two minutes thirty-five seconds. If the child were in a good temper to begin with it would hang quite placidly until its fingers began to slip, when it at once evinced distress, and screamed lustily as if from a fear of the consequences of falling. An examination of the foot of an infant showed that it was much more hand-like than that of the adult. The heel was much narrower than in after life, and the fore part of the sole, instead of presenting a rounded smooth surface, was flat or even concave, with creases like those of the palm of the hand. The author was not aware that any explanation could be given of these lines, so characteristic of a prehensile organ, on the foot of the human infant, other than that they were vestiges of an arboreal state of existence. He believed that it was due to the habit of the young clinging to the body of a parent who would require to use all her limbs for climbing.

Dr. Hepburn read a paper on the Integumentary Grooves on the Palm of the Hand and Sole of the Foot of Man and the Anthropoid Apes.

In a communication on the Contemporaneity of the Maori and the Moa, Mr. H. O. Forbes gave an account of the exploration of a cave in the neighbourhood of Christchurch, which had been closed by the landslip of a great part of the mountain at whose base it lay. From the remains of the last feast partaken of by the dwellers in this cave, it was clear that Moa eggs had been eaten by them, and therefore that the bird that laid those eggs was contemporaneous with the eaters. The ornamentation of the implements, &c., found in the cave proved that the cave-dwellers were true Maoris.

In the afternoon Dr. Garson opened a discussion on Human Osteometry, in the course of which Sir William Turner explained and demonstrated his method of taking the capacity of crania by the use of shot poured into the cavity of the skull through a funnel, the spout of which was 2 cent. long and 2 cent. in diameter. It was claimed for this method that it gave the actual capacity and did not over measure it as is the case with the plan adopted by Broca.

On Tuesday Dr. J. G. Garson exhibited some composite photographs of United States' soldiers.

Dr. Francis Warner contributed some Observations as to the Physical Deviations from the Normal as seen among 50,000 Children. The most important defects were found to be those of the cranium as indicated by the proportion among them delicate, dull, and with nerve disorder or weakness; many of these cases are doubtless due to rickets. Small heads were especially common among girls, the only defect to which they seem specially liable. The greatest amount of defectiveness did not occur in the poorest districts; for in the wealthier parts of London 12½ per cent. showed deficiency, while in the poorer districts only 7 per cent. showed defects.

The following papers were read by Prof. A. Macalister:—On Skulls from Mobanga, Upper Congo; On some Facial Characters of the Ancient Egyptians. It was remarkable how little variety was to be found in the heads of these ancients. The hairs of the eyebrows were small, and that on the head was not woolly but wavy. The nose was well formed, usually prominent, rather high-bridged and narrow. The nostrils were narrow, and very rarely was there much of a moustache. The chin was narrow and tapered. There were no traces of holes in the lobes of the ears. Prof. Macalister also read a paper On the Brain of an Australian.

Dr. Garson read a communication On some very Ancient Skeletons from Medum, Egypt. These skeletons were somewhere about 6000 years old, and their most interesting feature was that in the upper and lower limbs they had markedly negro characters. In the pelvis they had intermediate characters between the Egyptian and the Negro, while in the head they had well-marked Egyptian characters.

The following papers were also read:—C. Phillips, On a Skull from Port Talbot, Glamorganshire; Dr. R. Munro, On Trepanning the Human Skull in Prehistoric Times; E. H. Man, On the Use of Narcotics by the Nicobar Islanders, and certain Deformations connected therewith.

The reports of The Indian Committee, of The Prehistoric Remains of Glamorganshire Committee, of The Elbolton Cave Committee, and of The Prehistoric Inhabitants Committee were submitted.

In the afternoon Mr. G. W. Bloxam exhibited The Philograph—a Simple Apparatus for the Preparation of Lecture Diagrams, &c., and Dr. Louis Robinson showed a series of photographs illustrating his paper on the prehensile power of infants.

CONFERENCE OF DELEGATES OF CORRESPONDING SOCIETIES.

FIRST CONFERENCE, AUGUST 4, 1892.

THE Corresponding Societies' Committee was represented by Prof. R. Meldola (chairman), Sir Douglas Galton, Mr. G. J. Symons, Mr. W. Whitaker, Mr. E. B. Poulton, Mr. Cuthbert Peek, Dr. Garson, and Mr. T. V. Holmes (secretary).

The Chairman, after welcoming the delegates to the seventh conference which had been held under the new rules of the Association, said during the seven years of their existence they had, he ventured to think, done some good work for the Association and for themselves. They occupied now in relation to the Association very much the same position as one of its sectional committees, and for that they were very largely indebted to Sir Douglas Galton, who had very keenly watched their proceedings, and had taken a great interest in them. The report of the committee was then submitted, and the different subjects which had engaged attention during the year were dealt with under the heading of the Association Sections to which they belonged.

In Section A the Chairman introduced the subject of Temperature Variations in Lakes, Rivers, and Estuaries, but no delegate specially interested therein being present, the Conference proceeded to that of Meteorological Photography. Mr. Clayden and Mr. Symons spoke of the desirability of photographs illustrating the damage done by whirlwinds and floods, and Mr. W. Watts (Rochdale) said that the Society he represented was taking up the subject. Mr. Symons mentioned the Helm Wind of Crossfell and the peculiar cloud accompanying it, photographs of which would be useful. Mr. Watts stated that a difficulty in photographing the effects of floods arose from the state of the weather during their occurrence, and Mr. Cushing (Croydon) exhibited photographs of a recent thunderstorm. The Chairman then remarked that Mr. Kenward (Birmingham), who was unable to be present, had sent a letter stating that for some years in Birmingham meteorological observations had been made in the building called "The Monument." Mr. Symons and Dr. Stacey Wilson discussed the mode of operations pursued at Birmingham.

After some remarks by Prof. Merivale, the Chairman, and Mr. Symons, the Conference passed on to Section B.

In Section B the Chairman introduced the subject of the conditions of the atmosphere in manufacturing towns, and Mr. Mark Stirrup (Manchester) and Mr. Watts (Rochdale) said that observations and experiments were being made thereon in their respective districts.

Mr. De Rance (Section C) stated that the 18th Report of the Committee on Underground Waters had been read that morning; that the Committee thought it should be reappointed, and that a volume containing abstracts of the previous Reports should be published. The Committee on Coast Erosion hoped to conclude its labours next year. The Committee on Erratic Blocks continued to do good work. The Local Societies could do much to assist this Committee by noting the position of boulders, and by preserving them from destruction. Prof. Lebour (Section C) postponed his remarks on Earth Tremors.

Mr. Watts (Rochdale) spoke upon the denudation of high-lying drainage areas, and some observations he had made on the amount of material brought down by flood waters, and the degree of protection given by heather, grass, and peat. Dr. H. R. Mill said that something had recently been done in Germany to ascertain the amount of sediment in river water. He thought it very desirable that a series of observations should be made to determine the relative values of woodlands and heather in protecting land, and was inclined to suggest the formation of a Committee for that purpose. Mr. Watts said he would be glad to give information as to the methods followed in Rochdale.

Geological Photography.—Mr. Arthur S. Reid (East Kent) said that Mr. Jeffs had asked him to speak on the work of this Committee. The number of photographs amounted to about 700. He exhibited a specimen volume of photographs, and explained the way in which they were mounted and bound. He thought it important that some uniform plan of photographing geological subjects should be adopted, and that the plates used should be orthochromatic or isochromatic. Mr. W. Gray then spoke of the photographic work done by the Belfast Naturalists' Field Club, and Dr. Stacey Wilson of that of the Birmingham Philosophical Society; Mr. J. Barclay Murdoch mentioned the course proposed by the Geological Society of Glasgow, and the Chairman recommended the use of orthochromatic plates.

The Chairman invited remarks on the destruction of native plants and of wild birds' eggs. The Rev. E. P. Knubley (Yorks. Nat. Union) alluded to the Report presented to Section D on the disappearance of native plants and its causes. Mr. Watts said that two or three members of the Rochdale Society proposed to work at this subject. Mr. Mark Stirrup had a short paper by Mr. Leo. H. Grindon on the disappearance of wild plants in the neighbourhood of Manchester. The Chairman thought it might be read at the second conference. Mr. Cuthbert Peek remarked on the great difficulty of obtaining a conviction in cases in which ferns and other wild plants had been taken from private grounds.

Destruction of Wild Birds' Eggs.—The Rev. E. P. Knubley said terrible damage had been done by the destruction of birds' eggs. It was a serious matter, but it was very difficult to know what to do in regard to it. For instance, take the case of the great skua, which nested in the Shetland Islands; in 1890 it is said that not a single chick was reared on the whole of the Foula colony. Every egg was taken, and in 1891 all the eggs of the first laying were taken by the inhabitants and sold to dealers. Other rare birds which nested in the Shetland Islands were also persecuted. He had it on good authority that last year not more than two or three nests of the red-throated diver got off their young; and the black-throated divers were not more fortunate. One shilling apiece was given by dealers for the eggs of the red-throated diver and 10*s.* a brace for those of the black-throated diver. The whimbrels, which also nested on the same islands, had been reduced to about twenty pairs, and were likely to disappear. The red-necked phalarope was very much in the same circumstances. The dealers gave a commission to a local man, who was to get about 3*d.* a dozen for every egg collected of all sorts and kinds. The local men in turn got the herd boys to sweep the country of every egg they could lay hands on, big and little, and for these they got about 1*d.* a dozen. That was one way in which parts of Scotland had been regularly swept, and that in spite of such protection as the owners could afford. They had men who followed about strangers all day, but the natives took the eggs at night. Then, again, one might mention that one heard that in Edinburgh there was a gentleman who made it his boast that he had over 100 eggs of the golden eagle. What was to be done with a case of that kind? In some parts of England things were not any better. The nesting stations of the lesser tern which existed on the Fifeshire coast, the Lincolnshire coast, and at Spurn, in Yorkshire, would shortly disappear altogether. The oyster catcher and the Arctic tern had practically ceased to nest on the Lincolnshire and Yorkshire coasts, and the ringed plover was much scarcer than formerly. The redshanks and greenshanks had in many parts also been persecuted to the death. The nests of the bearded reedling, whose breeding station in the British Islands was the Norfolk Broads, had been to his own knowledge systematically poached for sale for a number of years. The only hope seemed to him to be in the creation of a public feeling against the extermination of these birds. It would be difficult to advocate anything like legislation. The most practical plan he had seen was this—that the Imperial Legislature should grant powers to the County Councils to protect known nesting-places in their districts for certain months of the year, say from April 1st to June 30th. Such a plan would be simple, and might be effective; but for one thing they should endeavour to do all in their power to help the owners and occupiers of land to protect the birds and their eggs during the breeding season. They might also see if they could not enlist the aid of the gamekeepers, who, with the farmers and proprietors, were beginning to find out that all birds were not their enemies. Collectors and dealers should also be discouraged. Just as he came there that day he had been told that 200 eggs of the stormy petrel had been taken from one island on the west coast of Ireland and given to one dealer.

Mr. E. B. Poulton, Oxford, said that if they discouraged the purchase of eggs, the trade of the dealer would soon cease.

Mr. G. J. Symons said it was an old saying that there would be no thieves if there were no receivers; and possibly there would be no dealers if there were no collectors. They should discourage as much as they could this spoliation of the nests of rare birds.

Mr. Mills, Chesterfield, thought it would do good if some small recognition were given to gamekeepers to assist in protecting the nests of the birds.

The Chairman asked if it would not strengthen the hands of Mr. Knubley if the meeting was to pass some resolution on the subject.

Sir Douglas Galton hoped any resolution of the kind would make an appeal to egg-collectors.

A Delegate suggested that it might do some good if the name of the Edinburgh gentleman with the 100 eggs of the golden eagle were published.

Mr. Whitaker suggested that the gentleman with the eggs should have the feathers of the birds also presented to him with the addition of a little tar. (Laughter.)

Mr. Knubley said he would submit a resolution at the next conference.

In Section E the Chairman remarked that last year there had been a discussion on the cost and antiquity of ordnance maps. Sir Douglas Galton said that a Departmental Committee was inquiring into the matter. Mr. Sowerbutts spoke of the badness of the teaching of geography in schools, giving examples from examination papers.

Flameless Explosives.—Prof. Merivale (in Section G) said he had nothing to report. The Durham strike had interfered with their arrangements, the proposed laboratories having been utilized as stables.

Under Section H Dr. Garson reported that there had been no applications to the Committee last year for aid in connection with anthropological exploration. He contended, however, that local bodies, when they meant to make such explorations, should give them notice. Valuable hints could be given them as to how they should proceed. Notice was also taken by Dr. Garson of certain anthropometric inquiries which were being conducted as to the effects on the health and physique of the public school system.

The Secretary, at the request of the Chairman, read an extract from a letter of Mr. Kenward, of Birmingham, giving particulars of an anthropometric laboratory established at Birmingham, like that of Mr. Francis Galton at South Kensington. Mr. Watts and Dr. Garson added a few remarks. The Chairman proposed that a claim should be made for the usual grant towards carrying on the work of the Corresponding Societies Committee, and the Conference adjourned.

SECOND CONFERENCE.—August 9.

The Corresponding Societies Committee was represented by Prof. R. Meldola (Chairman), and Messrs. Symons, Whitaker, Cuthbert Peek, Garson, Poulton, Rev. Canon Tristram, Sir Rawson Rawson, and T. V. Holmes (Secretary).

The Chairman made a proposal that in future some subject in which the delegates were generally interested should be brought as a short paper before the conference, such as the management of local museums, and the relations of County Councils to technical instruction, and the working of the Technical Education Acts. This was considered an excellent suggestion. Mr. Symons mentioned that he had arranged with Mr. Griffiths that delegates on the first day of the meeting of the British Association should be supplied with copies of the reports on subjects in which they were interested. This would give them longer time than they had at present to make themselves acquainted with the work which was being done. Mr. Robert Brown thought it would be a good thing if the printed report of the proceedings of the conference of delegates could be sent to the delegates earlier than at present. After some additional remarks from Mr. Cushing and the Chairman, the meeting proceeded to sectional work. In connection with the meteorological work in Section A, Mr. Symons spoke of the value of making observations on the temperature of underground waters, especially when new wells were being formed; and Mr. Whitaker remarked on the equally important point of the fluctuations of water in wells.

In Sections B and C there was nothing to bring before the Committee. When the work of Section D was reached an interesting discussion took place on the disappearance of native plants. Mr. Mark Stirrup began the discussion by reading a short note from an eminent Manchester botanist on the state of the district in that respect round Manchester. Mr. Sowerbutts, Manchester, said he believed the gentleman from whom the notes had been read was largely responsible for the eradication of rare plants round Manchester, inasmuch as he published a very charming book indicating where they were to be found. (Laughter.) Mr. Coates, Perthshire, said their Naturalists' Field Club, in publishing accounts of excursions or notices in papers of rare flora, only indicated generally where these were to be found. And Mr. W. Gray said that the Belfast Nat. Field Club acted in a similar way.

The Rev. Canon Tristram, Durham, next addressed the delegates on the question of making their field clubs more useful. He strongly advocated that these clubs should combine natural history, archæology, and geology; and that their function should be, not to destroy, but to preserve all that was rare and curious in a district. Lately their field excursions in many places had been too much of a picnic party. On the subject of local museums, the Canon argued that, as a rule, these should only contain objects of local interest, and he suggested that an approach should be made to the County Councils in order to get assistance for forming and keeping such museums in order. In regard to spoliation of districts of rare plants and ferns, the Canon advocated the formation of a public opinion on this question. On the question of the preservation from destruction of the eggs of rare birds, the Rev. E. P. Knubley, Leeds, moved the following resolution, which was seconded by Mr. E. Poulton, Oxford, and agreed to:—

"The conference of delegates, having heard of the threatened extermination of certain birds, as British breeding species, through the destruction of their eggs, deprecates the encouragement given to dealers by collectors through their demands for British-taken eggs, and trusts that the corresponding societies will do all that lies in their power to interest and influence naturalists, landowners, and others in the preservation of such birds and their eggs."

On this subject Canon Tristram also spoke, and put in a strong plea for the preservation of birds of prey—pointing to the case of the mice plague in Dumfries and Lanark shires as a result of destroying the balance of nature by wholesale killing of birds of prey. The resolution brought forward by Mr. Knubley was cordially adopted by the meeting.

In Section E Mr. Sowerbutts said that he should like to be able to communicate during the year with other delegates who were interested in geographical education.

In Section H Mr. E. W. Brabrook brought under the notice of the delegates the Ethnological Survey of the British Isles, which it was proposed to undertake by a committee of the Association on the suggestion of the Society of Antiquaries, the Folk-Lore Society, and the Anthropological Institute. Schedules would be sent down to societies, and he asked the co-operation of the delegates. Mr. Brabrook agreed with Canon Tristram in thinking that archæology should be one of the subjects of study of a field club. Mr. Whitaker said that in his district the Hants Field Club always did its best to protect antiquities; and Mr. Gray said that at Belfast the Field Club not only tried to preserve ancient remains, but also photographed them. Some of these photographs he exhibited. Canon Tristram mentioned the difficulties Field Clubs sometimes had with clergymen who were over-zealous in church restoration; and Mr. Tate (Belfast) alluded to the exertions of his society on that point; while the Chairman thought the clergy were not always as black as they were painted in this matter. Mr. Brabrook made some remarks on the best mode of making an archæological survey, pointing out the best sources of information, as regards the way of carrying it out.

Finally, Mr. Sowerbutts thought better terms might be obtained from the railway companies for delegates and others travelling to meetings of the British Association. The Chairman and Mr. Symons promised to represent the matter to the Council of the Association, and the conference adjourned.

SCIENTIFIC SERIALS.

THE *American Meteorological Journal* for July contains the following articles:—On the appearance and progressive motion of cyclones in the Indian region, by W. L. Dallas. The object of the inquiry is to see whether the cyclones of the Indian Ocean originate from the unequal distribution of temperature over and above the earth's surface. The author favours the assumption that cyclones are a production of the upper atmosphere, and thinks that the evidence, although far from conclusive, goes to show that (1) cyclonic storms descend from and retreat to the superior layers of the atmosphere; (2) the whirl may travel along in the upper atmosphere, giving only faint indications of its presence at the earth's surface; (3) the movements of cyclones agree generally with what may be supposed to be the movements of a superior layer of the atmosphere.—S. A. Hill, a memoir, by Edna Taylor Hill.—The eye of the storm (conclusion), by S. M. Ballou. The cause of the clearness of the eye is attributed by the author to the deficiency of the air at the outer edge of the calm, owing to the deflective force of the earth's rotation and the upward and outward movements of the air before reaching the centre; the deficiency being supplied by a gradual settling of the air over the whole area, thus dissolving the cloud stratum and showing the blue sky. The author admits that the discussion of the subject shows the need of more observations concerning the phenomenon.—Recent efforts towards the improvement of daily weather forecasts, by H. Helm Clayton. The author states in a clear and interesting form the various rules which have hitherto been established, and draws attention to a law of averages discovered by Francis Galton, which might with advantage be used in weather forecasting, for, although only applied by Mr. Galton to heredity, it is probably universal. For example, if a storm during a given twelve hours has moved with a velocity below the average, the probability is that it will move with a velocity one-third nearer the average during the next twelve hours.—The other articles are—on the sea breeze, by W. C. Appleton, and temperature sequences, by H. A. Hazen, being an inquiry as to whether, if the temperature has been high or low for a certain period, we may anticipate the contrary condition shortly. The inquiry does not seem to have led to any result which could be turned to practical use.

Bulletin of the New York Mathematical Society, vol. i., No. 10 (New York, the Society, 1892).—The opening article is a review (pp. 217-223) of "An Elementary Treatise on the Differential Calculus by Joseph Edwards" (2nd edition, Macmillan, 1892), by Miss C. A. Scott. Whilst the reviewer praises the "lucid and incisive style," the well-chosen words and the well-balanced sentences, she does not fail to make a slashing attack upon details, and to point out "certain specially vicious features." There is considerable force in Dr. Scott's criticisms, and it is probable that a careful consideration of them will enable Mr. Edwards still further to improve his, in many respects, excellent treatise. The remaining short contributions are a note on resultants, by Prof. Haskell; and collineation as a mode of motion, by Dr. Bôcher (originally delivered as a lecture before N. Y. M. Society (pp. 225-231). The usual notes, new publications, and index close the first volume of this new mathematical venture.

IN the *Botanical Gazette* for June, Mr. A. F. Foerste has an interesting paper, illustrated, on the Identification of trees in winter.—Mr. Charles Robertson continues his notes on the mode of pollination of American plants.—Mr. A. P. Morgan describes two new genera of fungi belonging to the Hyphomycetes, *Cylindrocladium* and *Synthetospora.*

IN the *Journal of Botany* for July, M. G. Massee describes and figures a new marine lichen from the coast of Scotland, *Verrucaria lætevirens*, and continues his description of new species of fungi from the West Indies.—Mr. W. H. Beeby argues in favour of the occurrence of natural hybrids among plants. In the number for August, Rev. E. S. Marshall supports the claim of *Cochlearia grœnlandica*, and the editor that of *Sagina Boydii*, to be considered as British plants; both are figured. In the continuation of his Notes on *Potamogetons*, Mr. Arthur Bennett describes two new species, *P. Delavayi* from China, and *P. tricarinatus* from Australia.

THE articles in the *Nuovo Giornale Botanico Italiano* for July are all geographical. Among them Dr. A. N. Berlese and Signor V. Pegliore give a monograph of the Micromycetes of Tuscany, 293 in number. The list includes several new species, and one new genus, *Phæopeltosphæria*, belonging to the Sphæriaceæ.—Signor S. Sommier commences a very interesting description of the physical features of the lower valley of the Obi in Siberia, with some account of its botany.

IN Nos. 5 and 6 of the *Bullettino della Soc. Bot. Italiana*, most of the articles are also of local interest. Signor A. Jatta describes a new genus of lichens, *Siphulastrum*, from Tierra del Fuego.—Signor E. Baroni gives a full description of the anatomy of the fruit and seeds of *Eugenia myrtillifolia.*—Signor L. Re contributes an account of the spherites found in *Agave mexicana* and other Amaryllidaceæ.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, August 22.—M. Duchartre in the chair.—Heat of combustion of some chlorine compounds, by MM. Berthelot and Matignon. The method of the calorimetric shell was employed for determining the heat of combustion of certain acid bodies. Monochloracetic acid, $C_2H_3ClO_2$, gave + 174·2 calories at constant volume, and + 173·9 at constant pressure, as the result of two combustions with camphor in presence of arsenious acid. The values obtained for trichloracetic acid, $C_2HCl_3O_2$, were + 106·3 at constant volume, and 105·4 at constant pressure. Trimethylene chloride, $C_3H_4Cl_2$, burnt in the presence of an equal quantity of camphor, gave a mean of 3·900 calories per gramme of the substance.—On glyoxylic or dioxyacetic acid, by the same.—M. Pasteur, in presenting to the Academy a work by Dr. Daremberg on Cholera, its Causes, and Means of Guarding against it, called attention to the following points: "Dr. Daremberg, in one of the principal chapters of his book, protests with great force against the pollution of the water-courses by drain-waters, and equally against the pollution of the soil by the distribution of these waters on the land under cultivation. He thinks that the germs of cholera, in the form of the bacillus which produces it, can remain living and virulent in the soil for several years, and eventually lead to the spread of the disease. Thus the cholera in the environs of Paris would have originated in cholera germs preserved since the last epidemic in 1884."—Thermo-chemical study of certain organic bodies with mixed functions, by M. Léo Vignon.—Quantitative determination of peptone, by precipitation in the state of peptonate of mercury, by M. L. A. Hallopeau. This method is claimed to be superior to the polarimetric, the calorimetric, and the absolute alcohol methods as being a complete precipitation admitting of more trustworthy measurements than the first, and less difficult than the second. A solution of peptone, which must be neutral or very slightly acid, is precipitated by a large excess of mercuric nitrate. The precipitate of mercuric peptonate, white, flocculent, and bulky, falls almost immediately to the bottom of the vessel. It is allowed to settle, and then poured on to a filter of known weight, washing with cold water until no precipitate is produced by sulphuretted hydrogen. The increase in the weight of the filter, dried at 106° to 108°, represents the weight of the peptonate of mercury; multiplying this by 0·666 gives the amount of peptone present. The mercuric nitrate is readily obtained from the "pure" commercial nitrate. Since this contains an excess of free nitric acid, which partially redissolves the peptonate of mercury, the acid must be removed by heating the nitrate with ten times its weight of water for fifteen or twenty minutes, filtering and heating to near boiling in a porcelain capsule. Then stir and add a few drops of carbonate of soda until the precipitate of oxide of mercury is no longer redissolved.—Etiology of an enzootic disease of the sheep, called Carceag in Roumania, by M. V. Babes. In the very fertile and often submerged islands of the Danube, where the shepherds from Roumania and Transylvania congregate, and where there are always hundreds of thousands of sheep, a disease occurs among them, especially in May and June, to which often a fifth of the herd will succumb, especially if it should have been brought thither from a distant pasture. It is an acute malady of a febrile nature, combined with hæmorrhage and œdema, and always with hæmorrhagic and sometimes necrotic inflammation of the rectum. In the red corpuscles of the blood are found round, immovable cocci, often undergoing subdivision. They are very similar to those observed in the corresponding cow-disease known in America as the Texas fever.—On a new chemical function of the comma-bacillus of Asiatic cholera, by M. J. Ferran. The growth of this microbe is always rapid and luxurious in the ordinary culture solutions; if they contain milk-sugar, it is incomparably more so; but the growth ceases entirely as soon as the solution becomes acid by the development of lactic acid, and the vitality of the microbe is extinguished. It seems reasonable to employ lactic acid in lemonade against cholera, and to aid its action by the anexosmotic power which morphin offers us; this substance would perhaps hinder the absorption of the toxic substances, and would prolong the action of the lactic acid by opposing its rapid elimination.

THE HIGHER THEORY OF STATISTICS.

Die Grundzüge der Theorie der Statistik. Von Harald Westergaard, Professor an der Universität zu Kopenhagen. (Jena: Verlag von Gustav Fischer.)

THIS is an important contribution to the Calculus of Probabilities and the higher theory of Statistics. The foundation of experience on which the whole edifice of probabilities is based has been strengthened and extended by the new material which Prof. Westergaard has deposited. Here, for instance, is one of his experiments:—From a bag containing black and white balls in equal numbers, he drew (or caused to be drawn) a ball 10,000 times, the ball being replaced in the bag and the bag shaken up after each extraction. He records not only the total numbers of each colour, but also the number of white balls in each of 100 batches, each numbering 100 balls, also in 50 batches each of 200 balls, and so on. The diminution of the relative deviation from the average as the size of the batch is increased comes out clearly. On an equally large scale Prof. Westergaard has observed the proportion of prizes to blanks in batches of tickets drawn at a lottery; and the frequency with which different numbers, drawn under conditions such that one number was as likely as another, were observed to occur actually. He has similarly tabulated the frequency with which the different digits 1, 2, 3, &c., terminate certain officially recorded amounts, the "kontis" of a savings bank, of which documents he has examined 10,000. These experiences afford new confirmation to the first principles of the calculus: namely, the fundamental fact of statistical regularity which the definition of probability involves, and the postulate that certain events are independent of each other in such wise that, if the probability of each be $\frac{1}{2}$, the probability of the double event is a quarter.

Ascending from these simple experiences, Prof. Westergaard reaches by a new and easy route the formula for the measure, or *modulus*, of the extent to which the observed number—*e g.* of white balls in a batch of 100 or 1000—is likely to differ from the most probable number; in the instance just given $100p$ or $1000p$, if p is the probability of drawing a white ball. The sought expression, it is presumed, must be a *symmetric* function of the probability of the event (drawing a white ball), which we have called p, and the complementary probability (drawing a non-white ball), viz., $1 - p$. This hint enables us to decipher from the records of experience that the modulus is proportioned to $\sqrt{p(1-p)}$. The influence of the *size* of the batch upon the extent of the deviation is similarly elicited from observation. Thus with a minimum of mathematical equipment, by easy steps and through an unpretentious *a posteriori* gate, we are led into the very stronghold of Probabilities—if not to the law of error itself, at any rate to one of its most important properties.

Prof. Westergaard has not only popularized the law of error, he has also proved it. He has added considerably to its evidence, by observing in an immense number of instances the exact correspondence between fact and theory. We must content ourselves with citing one set of instances. Ten thousand balls having been drawn at random, as above mentioned, and the composition of each batch of a 100 being examined, it was found that for twenty-five out of a hundred such groups the number of white balls lay between 49 and 51 (inclusive)—limits distant ± 1 from 50, the most probable number. For forty out of the hundred groups the number of white balls lay between the limits 50 ± 2. And so on. The observations are exhibited and compared with theory in the annexed table:—

Number of batches in which the number of white balls is between certain limits.		Limits.
Observed.	Calculated.	
25	24	± 1
40	38	± 2
50	52	± 3
70	73	± 5
85	87	± 7
95	96	±10

The multiplication of correspondences like this, the concatenation of evidence in favour of the law of error which the author has put together in his fifth chapter, is very cogent.

Another sort of verification to which the law of error is submitted is to compare it with the explicit binomial to which the exponential law is an approximation. This approximation is closer than may be supposed. For example, if a hundred balls be taken at random, each ball being as likely to be black as white, the probability of obtaining exactly 50 balls, as evaluated by the binomial theorem, is ·080, as approximately determined by the exponential law of error is also ·080. The probability of obtaining either 49, 50, or 51 is, according to the exact calculation, ·236, according to the approximative formula, also ·236. And so on.

Among other contributions to the calculus which Prof. Westergaard has either adduced from authors rarely read, or himself deduced, may be noticed his elegant treatment of the case where the probabilities of two alternative events (say, drawing white or black balls) are not equal (p. 70). Suppose that the probability, say p, of one event is very small, then the formula for the deviation of the number of white balls actually drawn from the number most likely to be drawn, viz. np, admits of simplification. The "mean error" ($=\textit{modulus} \div \sqrt{2}$) is in general ... ($\sqrt{np(1-p)}$); in the particular case it becomes approximately $\sqrt{np}$. A further simplification may be explained by an example. Suppose that we know the number of deaths, say 900, per unit of time in a certain population. Then, without knowing the number of the population, or without taking the trouble of referring to it and calculating the death-rate, we may determine approximately the fluctuation to which the number of deaths is liable. For the measure of that fluctuation the "mean error," is approximately $\sqrt{np}$; n being the number of population, a large number, and p the death-rate, a small fraction. Now np is 900, and accordingly 30 is the mean error, that is, assuming that the urn in which the lots of Fate are shaken—"omnium Versatur urna serius ocius Sors exitura"—is constituted as simply as the urn in which we have supposed black and white balls to be shaken up. This is a question in Applied Probabilities to which we are just coming.

Prof. Westergaard's applications of the calculus to statistics are even more striking than his developments of the pure theory of probabilities. The law of error may be applied to concrete phenomena in two cases: where the fluctuation of averages follows the analogy of the simpler games of chance—as we just now assumed with regard to deaths—and where this condition is not fulfilled. Prof. Westergaard's contributions belong chiefly to the first class. He has considerably added to the instances discovered by Prof. Lexis, in which a set of ratios—such as the proportion between the mortality of male and female infants in different years—are grouped according to the same law of dispersion as the percentages of white balls in a set of batches drawn at random from an urn containing black and white balls mixed up in a certain proportion. The uses of this discovery are twofold—negative and positive. In the first place, we may be deterred from a search after causes which is hopeless. In the typical instance of the urn and balls it would be vain to trace the reason why any particular ball, or set of balls, extracted should be white (or black). We cannot hope to analyse the "fleeting mass of causes"—as Mill calls Chance—upon which the event depends. We may have been able to break up our batches of balls into two classes, say rough and smooth, such that the rough balls are extracted from an urn containing mostly white, while the smooth balls are more frequently black. But when this process of "depouillement" has been carried as far as possible, when we have reached the ideal type of a single urn and constant proportions, then the investigation of causes halts. Then it is only crazy gamblers who hope to discover a principle underlying the "runs" of black and white balls. We have reached the bounds of the territory of science; beyond there is only the sea of chance. Prof. Westergaard has not only indicated this limit, but also pushed many of his investigations up to it.

These considerations do not preclude us from applying the theory of error to detect delicate distinctions such as the difference between a loaded and a perfect die, which make themselves felt in the averages of great numbers of observations. In fact, it is by the mathematical method that we can best determine whether a difference between two averages is significant of a real constant difference, or only apparent and accidental. Prof. Lexis, and Dr. Duesing after him had applied this method to the investigation of the conditions under which the excess of male over female births is greater or smaller than usual. Prof. Westergaard shows that the method is applicable to many other subjects, among which the mortality at different age-periods promises to be most useful. We could wish, indeed, for more copious evidence in favour of the premise that the mortality of a population at a certain age-period (say of clergymen or innkeepers between the ages 35-44. See *Grundzüge*, p. 82, with context, and *cf.* p. 52) fluctuates according to the analogy of games of chance.

Here the question arises: must the phenomenon under consideration be known to vary after the manner of balls extracted from an urn, in order that the mathematical method may be applicable? Certainly the apparatus of the law of error—probable and improbable deviation—may be employed to ascertain whether the difference between the average heights of two groups of two men is significant or accidental; though in this case the modulus (or mean error) does not follow the analogy of the simpler games of chance. Might we not similarly compare the *general* mortality of two sections of population, although the dispersion of such death-rates about their average is much greater than it should be on the hypothesis of pure sortition. The advantage, indeed, which we have above distinguished as negative, would no longer exist in this case. But might not the positive advantage still be enjoyed in some degree? Prof. Westergaard, so far as we have observed, is silent on this topic.

We have left ourselves too little space for noticing Prof. Westergaard's other contributions to applied Probabilities. His treatment of Insurance, together with the adjacent theory of Life-Tables, involving the arts of Interpolation, may dispute with Cournot's classical chapters the honour of forming the best introduction to the subject for the general reader—the reader prepared by a general mathematical, as distinguished from a special actuarial training. Nor must we pass over the chapter in which the author surveys "economic" (exclusive of Vital) statistics. He has here occasion to employ largely the important principle of inference from samples. For instance, in order to discover the amount of wood in a country, we should first select one or more sample surfaces (*Probe-flächen*), and a sufficient number of sample trees thereat, and then measure the quantity of wood on those trees. "From the figures so found conclusions can be drawn as to the whole sample-surface, and from those to the total quantity of wood in the country." So in order to determine the quantity of milk, we must proceed by way of *Probe-kühe.* The method of samples is no doubt a potent instrument when wielded by a trained hand like Prof. Westergaard's. We may perhaps extend to economics generally what he suggests with reference to its statistical side: that a given effort and expense may be better laid out in obtaining a detailed knowledge of a few parts with a general view of the whole, rather than a more uniformly distributed information.

The last part of the work is devoted to a history of statistics; not a chronicle, but such a history as a great tactician would write of past wars. The criticism of Quetelet's methods is particularly instructive. In connection with Quetelet we may note—without assenting to—one of the Professor's objections to the principle of the "Mean Man." It is in effect the same objection as Cournot raised: that the average of one limb derived from measuring several specimens might not fit the average similarly found as the type of another limb. The model man constructed by putting together these averages of parts might prove to be a monster.

In conclusion we venture to express the hope that this important treatise may be translated into English; in order that the insular student may not have to encounter the difficulties of German and Probabilities at once. We might advise the translator to follow the excellent English custom of prefixing descriptive headings to all the tables. As they stand, a close attention to the context is sometimes required in order to be quite certain of the principle in which figures referred to as "calculated" have been obtained. We refer chiefly to the fourth chapter. There occur also, in the second chapter, some terms vital to the meaning, which may require to be interpreted for the benefit of the English reader; e.g. *Zahlenlotto*, *Klassenlotterie*, *Kontis* relating to the *Sparbank* "Bikuben" in Kopenhagen.

F. Y. E.

THEORETICAL PHYSICS IN ITALY.

Trattato di Fisico-Chimica secondo la Teoria Dinamica. Opera Postuma di Enrico dal Pozzo di Mombello. (Milano, 1892.)

THIS is an elementary treatise from the hand of the late Prof. Mombello, of the Free University of Perugia. In the general nature of its contents it might be compared to Prof. Ostwald's *Allgemeine Chemie.* It is, however, much smaller; and is indeed less of a systematic treatise than a condensed statement of the many principles and laws on which physics and chemistry are built. The English terms physics and chemistry have, under the influence of our examination systems, become so stereotyped in meaning that neither term could fitly describe the character of this *Trattato di Fisico-Chimica.* The time-honoured division of subjects would ill fit into its plan. Dynamics, properties of matter, heat, light, sound, electricity, and magnetism are certainly all treated in their more theoretical aspects; but there are also introduced the laws of chemical combination and the atomic theory, which give the book a character possessed by none of our English treatises on physics. A brief sketch of its character may not then be wholly valueless.

The treatise is divided into five parts, under the headings *Dinamica*, *Azione Moleculare*, *Elettrologia*, *Luce e Colore*, *Filosofia Scientifica.*

The first part contains much that we understand as Dynamics; but it contains a good deal more. In chapter I. (*Moto ed Energia*) physics is described as the science of motion. The universal law of nature is the law of causality, after a brief discussion of which we are introduced to four general principles—namely, the law of the conservation of mass, the law of the equality of action and reaction, the rectilinear action of force, and the composition of motions. Then follow two *General Physical Laws*, the conservation of energy and the transformation of energy (*la correlazione ed equivalenza dei moti*). Thereafter are introduced somewhat less general formulæ, which are distinguished as *Definite Physical Laws* and *Definite Chemical Laws.* Of the former, two examples are given—namely, "Pascal's Law" concerning the transmission of pressure in a liquid, and "Dalton's Law" that there is no physical action between the particles of gases, which are not chemically combinable. Then of the definite chemical laws four are particularised, being distinguished by the names of Lavoisier, Proust, Avogadro, and Cannizzaro, the last being a modified statement of Dulong and Petit's law of the specific heats of the elements. The rest of the chapter is devoted to a discussion of inertia, of Newton's laws of motion with special reference to the second interpretation of the third law, of kinetic (*attuale*) and potential energies of action at a distance, and of the conception of stress (*conflitto*) between particles. Chapter II. (*Composizione dei Moti*) is purely kinematical. In chapter III. (*Velocità moleculare*) the physical molecule is led upon the stage. Cohesion, viscosity, rigidity, porosity, volatility, critical points, crystalline form, and gravitation—in a word, the essentially molecular and *dynamic* qualities of bodies—are touched upon; and the whole finishes with an elementary treatment of the kinetic theory of gases, including an account of Crookes's experiments on radiant matter. It is satisfactory to notice that Prof. Mombello, like Prof. Ostwald, has the boldness to speak simply of Boyle's Law untainted by the Marriotte blend. This, of course, is merely historic justice. On the other hand, surely Herapath deserves mention as one of those who aided in the development of the kinetic theory of gases.

This early introduction of the kinetic theory has no doubt its merits; but a more logical course would have been to give in the first place some notion of the real meaning of temperature. This is touched upon in the immediately succeeding chapter, *Teoria termo-dinamica*, which forms Chapter I. of Part II. The treatment here is certainly peculiar. Two theorems (*enunciati*), we are told, are to be taken for the study of heat. The first embraces Carnot's doctrine of the logical necessity for a complete cycle, and his great principle of the reversibility test. Lord Kelvin's definition of temperature is brought in as a kind of corollary and dismissed in a few sentences. We hear no more of Carnot. "The second *enunciato* is concerned with the fact that in the universe an immense indefinite quantity of heat is being generated constantly during the formation of the stars." Then follows a brief sketch of some of the conclusions of spectroscopy, leading up to a broad discussion, in terms of the molecular theory, of the meaning of temperature, and of radiant energy in its four-fold aspect—thermal, luminous, chemical, and phosphorescent. After this thermodynamics, in the usual significance of the term, is presented under the guise of two propositions ascribed to Hirn. These propositions are, to all practical intents and purposes, simply the two laws of thermodynamics. But we search in vain for any reference to Joule; while Rankine and Clausius are merely mentioned as having proposed a demonstration of Hirn's second principle! Now Hirn deserves all credit for his experimental corroboration of the truth that only a fraction of the heat which leaves the boiler is transformed into useful work; but to magnify his labours in the way indicated is surely an inversion of history. Moreover there is no hint as to the relation between Carnot's reversible engine and the second principle; and the absolute zero of temperature is defined only in terms of the gaseous laws. Of entropy and the dissipation of energy we find no trace.

The succeeding chapters of Part II. are devoted to such subjects as the atomic theory (chemical) and the various aspects of capillarity, diffusion, osmose, &c. A brief account is also given of electro-chemistry, although electrical phenomena in general are not discussed till later. The seven chapters of Part III., in which electricity and magnetism are treated, form a highly condensed and instructive compendium of fact and theory, the two not always, perhaps, very clearly distinguished.

Chapter V. is concerned with "The Induction Balance of Hughes"; and here, for the first and last time, we encounter the name of Joule, who appears as the discoverer of the elongation of iron in a magnetic field. This is, of course, thoroughly accurate; but why, we naturally ask, is there no mention of Joule's Law of the heating accompanying conduction of electricity? The whole question of resistance is, indeed, barely touched. It is difficult to imagine by what process of reasoning such an important subject is omitted in a book which positively bristles with laws and principles named after their discoverers.

This method of cataloguing physical laws—for it is little else at times—has its advantages, especially from an examinee's point of view. It is doubtful, however, if it can be carried out consistently. Prof. Mombello certainly has not done so, although in the majority of cases he seems to be historically sound. One objection to the method is that, as it is impossible to group physical principles, like geometrical propositions, in a logical series, and as physical principles belong to different axiomatic, experimental, or hypothetical grades, there is a strong tendency, in a compendium of the kind we are reviewing, to present these principles in a false perspective. There is no doubt, however, that Prof. Mombello has placed in the hands of the countrymen of Galilei an instructive and suggestive treatise bearing on the varied phenomena of molecular physics. There is editorial carelessness in the spelling of foreign names, and serious faults of omission of the character discussed above. But the teaching is in general sound, and Part V. fitly closes with an account of Maxwell's electromagnetic theory of light, and a discussion of the character of the ether.

C. G. K.

THE MICROSCOPE IN THE CLASS-ROOM AND LABORATORY.

The Microscope and Histology for the use of Laboratory Students in the Anatomical Department of the Cornell University. By Simson Henry Gage. Third edition. Part i. (Ithaca, New York, 1891.)

THIS is a practical handbook by a thoroughly practical histologist. It is an expansion of an earlier and more concise treatise, written not for the amateur and the dilettanti, but for the laboratory student.

The recognition of the need of such a handbook is in itself an evidence of the practical character of its author, and of his knowledge of the wants of the serious student. To follow intelligently the best and most suggestive histological teaching requires more than a passing or perfunctory knowledge of the use of the microscope; and this can only be really acquired by those who have at least an elementary knowledge of the principles upon which this now really complex instrument is constructed. It has become an instrument of precision, and precise methods must be adopted in its use. This does not mean that it is more difficult to use than it was in the early years of the last quarter of a century; but it only implies that the principles upon which it is to be successfully employed should be thoroughly understood and practised.

Thus the apochromatic system of lens construction is an immeasurable gain, an improvement so great that its amount cannot be exaggerated; and these lenses are, if anything, rather easier to use than those of the older achromatic construction; but if the principles of their construction, and consequently the principles involved in the employment of them, be not understood and carefully practised, they yield results entirely unsatisfactory.

Again—and this is a point not referred to by Prof. Gage—those who may be provided with a good battery of achromatic lenses, and do not desire to face the cost of changing these for a series of apochromatics, may come wonderfully near the best results of the finest apochromatic objectives by the use of real monochromatic light. To obtain this with complete certainty, using any monochrome of the spectrum we may desire, with good lamplight, is now not only possible, but easily within the reach of all, and in such a manner as to lend itself to employment with the condenser and any magnifying power it may be needful to apply; and by this means not only is a good achromatic lens, as it were, elevated optically into an "apochromatic," but its numerical aperture is increased—the great desideratum, all else being equal, of good optical performance.

These are indications enough to emphasize the importance to the medical student generally, and to the histological student in particular, of a book that will briefly and accurately give him a knowledge of the principles involved in the construction and employment of the microscope, upon his intelligent use of which so much depends, but to which, as a rule, so little time is devoted, and therefore so little knowledge is possessed.

We do not for a moment suppose that a treatise like this, however well conceived and carried out, can give efficient, to say nothing of exhaustive, knowledge of optical theory, principles, and the laws and conditions of construction so as to enable a student to become in this sense a master of microscopic manipulation and interpretation; but it will go far to enable him to go through his work as a student with an intelligence and insight otherwise unapproached; and what is still more important, it will give him the opportunity of acquiring ability to see in the preparations he is instructed to make, or which he is required to study, or which he makes of his own initiative, that which he is *not* directed to look for, and which may open up for him and his science new and important paths. But this cannot be done if the student is not, in a strictly scientific sense, using his instrument, and is therefore approximately certain of the propriety of the interpretation of what he has been able to make out in his preparation.

Prof. Gage has adopted a system of illustrations (which we think might have been of a more refined artistic character, with much advantage) which are concisely and in the main accurately explained, and are intended to cover the entire subject; definitions, descriptions, and textual illustrations are added, which, taken together give a completeness to the treatise, that thoroughly fit it for its intended purpose. In many points it is as a matter of necessity, from its very nature, inefficient. It can only indicate, and not exhaustively explain, many most important points. But to the intelligent student alive to his subject, these are but spurs to further reading; and the larger treatises, giving full explanations of the matter in hand, will not be long unread. In short this treatise lays the foundation for a thorough microscopical training, entirely adapted to the wants of medical students.

It is printed only on one side of the page throughout, so that the blank page is open for notes, and by using the opportunities presented with wisdom, the book may acquire, in the hands of an industrious student, a doubled value.

We may note that there are some points that even with the restricted object of the book we think might have received fuller, or even more accurate treatment. A fuller treatment might certainly have been given to the subject of "oblique light," which is very lightly touched; but which is none the less, to the partially instructed, whether medical student or ordinary amateur, one of the most prolific and frequent sources of erroneous judgment and entire misinterpretation; and we believe that no treatise on microscopic work, whatever its object, can be thoroughly efficient without giving it grave and careful consideration.

On the other hand it would have given greater value from the point of accuracy if the details given for the "Centring and arrangement of the Illuminator," by which is meant the sub-stage condenser, had been of a somewhat later period. On the use—the right use—of the condenser much of the best English work of the past quarter of a century has been spent. Happily German microscopists and opticians have during the past seven or eight years begun to perceive the value, nay, indispensable importance, of this apparatus, and the firm of Zeiss have, through Abbe, made successively chromatic, and subsequently achromatic condensers of increasing value. We trust they may be induced to follow English opticians and make apochromatic condensers, especially one adapted in numerical aperture to their latest optical triumph in lenses, viz., that possessing a N.A. of 1·60; the full value of which as an apochromatic objective can never be seen without it. It is a pleasure to note that Prof. Gage tells us that "for *all* powers, but especially for high powers," the condenser is of "great advantage." We believe it for the highest results, even with "low" powers, to be indispensable. But it will never be by the employment of "a pin-hole diaphragm . . . put over the end of the condenser" so that this aperture shall appear in the middle of the field, that the best possibilities of the condenser will be reached. The student is plainly told that the "optic axis of the condenser and of the microscope should coincide," but the best way of securing this coincidence is certainly not stated.

The blemishes of the book are nevertheless few, it has a decided purpose, and there is a large sphere for its action. We believe that another edition will not long hence be called for in which its author will not find it difficult to emend and expand it in certain parts, and possibly still further to enlarge it, and we will add that we think it may not only prove of value to the students in the Anatomical Department of the Cornell University, but also to others on both sides the Atlantic.

W. H. Dallinger.

OUR BOOK SHELF.

An Elementary Text-book of Magnetism and Electricity. By R. Wallace Stewart. Univ. Corr. Coll. Tutorial Series. (London: W. B. Clive and Co., 1892.)

In this work Mr. Wallace Stewart presents us with another of his excellent text-books on elementary science. Just as his treatment of the subject was concise and clear in his book on heat and light, so here he has followed the same lines, and has placed before the student, especially one who is preparing for the matriculation examination of the London University, a course in magnetism and electricity which will give him a thorough knowledge of the subject and a sound basis on which to make further study. The illustrations and diagrams will be found to form a valuable addition to the text, while the numerous examples at the end of each chapter, if thoroughly worked out, should give a student a good insight into the art of solving problems.

Key to Arithmetic for Beginners. By J. and E. J. Brooksmith. (London: Macmillan and Co., 1892.)

This key will be welcomed by all those who are employing Mr. Brooksmith's excellent arithmetic. It has been prepared especially for the use of teachers, who will find it a valuable aid in their work, but no doubt it will be largely demanded by those who are studying this subject for themselves, for much may be learnt by a judicious use of such a book. The examples, so far as we have been able to see, have been very carefully and concisely worked out, and many difficulties that usually arise have here received careful attention.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

International, Geological, and other Records.

My friend Mr. Minchin's letter has opened a question that I have been ruminating for a very long time. We occasionally hear of the organization of science, but the very ABC is at present neglected, or carried out in a spasmodic and disjointed manner. Let us take for example geology. We have several attempts at a catalogue and review of its yearly literature, of which I give the following examples. First comes the "Geological Record," a publication very well in its way, but making its appearance at irregular intervals, and often much behind time. We have in Prof. Blake's Annual the attempt of a single individual to cope with a mass of literature that it is impossible for him to read, and treating of questions that no single person is or can be qualified to deal justly with. The very obvious result of this is careless reviewing, and general dissatisfaction of most authors whose papers are submitted to the abstracting process. I hope Prof. Blake will not take these words as a disparaging appreciation of his attempt, which I think does him much credit as a single-handed worker, but it will not satisfy the geologists in general. Next we have the "Annuaire Géologique Universel," for which great credit is due to Drs. Carey and Agincourt. Here we have the geological literature of each country treated separately, followed by a subject literature. Each article is compiled by a specialist in his own branch, and one who is able to form a just opinion of the work and appreciate the salient points of it. Altogether the organization of the "Annuaire" is on the right lines, but I understand it is not a financial success, and I have very grave doubts if it will continue, because the supporters of one publication cannot be the supporters of several. The motto "L'union fait la force" is as true in this case as in any other. Then again there is not that official character about it that there would be with international co-operation, supported by governments, scientific societies, &c. As two years' collaborator for the subjects of seismology and vulcanology I can give some of my experiences. In the first place it means a very big slice of time to read (for without this the thing had better be left alone) and review the annual literature of such subjects; for this there is no recompense whatever, but as I shall show actual money out of pocket. It is impossible for the reviewer, unless residing in such towns as London, Paris, or Berlin, to see all the literature of his subject. He, therefore, has to send out circulars, the expenses and postage of which, without counting labour of addressing, I found to come to about 2*l.* annually. A considerable proportion of these circulars are not even answered by those who have published papers on the subject during the year, and I am sorry to say that in one or two cases I have had a reply insinuating that I had been "*cadging*" for a copy of the author's paper or book. After the review is published come protests from authors (not many in my case, fortunately,) whom, out of common courtesy, time and money must be spent in answering. Finally, with every care such a work is far from complete. I would, therefore, hazard the following propositions:—A preliminary committee to be formed as soon as possible to study the question of international records of scientific literature. That such committee should determine the language of such records, the methods of organization of each separate subject committee, the means and resources of such, and invite the co-operation of other nations.

To my mind each record committee—say, for example, that of geology—should invite the specialists who are willing to collaborate to do so, should examine their manuscripts before going to print, keep a list of all known workers in that particular branch, and find as many subscribers to the work as possible. The central committee should nominate the subject committees, treat with governments, societies, and universities for support, and keep a loose card catalogue of all scientific investigators in the world, to whom should be posted annually a circular requesting the dispatch of their publications, if possible with a short abstract by themselves, to the reviewer of their special subject, the names and addresses of whom should be appended to the circular. In this way reduplication of reviewers circulars would not take place; and if a botanist wrote a paper on an earthquake, for example, he would be reached by the application from the vulcanologist as well as by the botanist. Finally, should profits accrue in the future, I would suggest that they be equally divided annually amongst the reviewers. I really hope that the subject will be taken by the horns before we reach—and we are near—a great scientific literary deadlock.

Harrogate, August 30. H. J. Johnston-Lavis.

A Suggestion for the Indexing of Zoological Literature.

It is obvious that the numerous records of all sorts which comprise the zoological literature of each year are only of use so far as we have access to and knowledge of them, and that their existence is actually a very serious encumbrance to those workers who are unable to make use of them.

It is self-evident that sooner or later, if zoology is to be preserved from chaos, every fact of any importance will have to be indexed for reference. Otherwise, nearly the whole lives of zoologists will come to be spent in libraries, until the thing gets so intolerable that some one suggests that we burn all the books, and start afresh from nature.

Of course, a great deal of indexing has been done, and is being done. The "Index Gen. et Spec. Anim." is well on the way, and the "Zoological Record" and other works of a like nature appear annually. But these are mainly records of names of species and genera described as new, and the "Zoological Record," admirable and invaluable as it is, is not always complete, nor in some sections (notably the last on mollusca) entirely accurate. Much indexing is continually being done in monographs, such as the Brit. Mus. Catalogues, and the value of this work can hardly be over-estimated, but here again it mostly relates to *species* as such. Then there is the Royal Society's "Catalogue of Scientific Papers," which is good so far as it goes, and the still more perfect Engelmann and Taschenberg. Putting aside, for the present, the question of indexing past records, would it not be a great advantage if we could begin now, and index everything as it appears? Possibly this could be done on the following plan:—

Let a society be formed, called, say, the Zoological Index Society, consisting of all writers on zoological subjects who will join.

The members of the society to be provided with uniform record slips at cost price, on which they will undertake to record *everything* in their writings that they believe to be important or new. These records might be under various heads, *e.g.*, the "semi-melanoid variety" of the leopard, described to the Zoological Society on November 20, 1883, might be indexed under *Felis pardus*, under *Melanism*, and under *Cape Colony*.

These slips to be sent to the secretary of the society, who would arrange them in alphabetical order, in cabinets provided for the purpose. The slips, under each special heading (*e.g.*, Species, Higher Groups, Variation, Distribution, &c.) would form continuous series. The slips of each year might be kept separate for six months, and then merged in the general index.

The members would be required to pay a subscription sufficient to cover the expenses of the above; but it would probably be possible to obtain assistance from some of the scientific societies, and the most suitable place for the index to be kept is doubtless the Natural History Museum. If this were accomplished, it would still be desirable to raise further funds, in order to increase the utility of the index in the following ways:—

(1) By obtaining an assistant secretary, whose duty it would be to copy out records from the index for workers residing in the country or abroad, at a certain small charge. The applicant might ask, *e.g.*, for *Limax*, or Jamaica, or Albinism, and would pay according to the number of records.

(2) By publications. Possibly some arrangement might be made with the Zoological Record Committee, and special publications containing the records relating to matters then of interest might appear as often as possible.

Volunteer work in indexing earlier works would be acceptable. Thus, some admirer of Darwin might be willing to index the works of that author. But in such cases a careful list should be kept of the books indexed, and every index should be complete. Presumably no one will dispute the utility of an index as proposed, but some may doubt the possibility of getting sufficient co-operation. If the idea of such an idex became familiar to writers, it can hardly be doubted that each would desire to place his writings on record along with the rest. If a man's writings are not worth this trouble, they are surely not worth printing, unless, of course, they are of such a nature (*e.g.*, educational works) as not to require indexing in this manner. Rain with a High Barometer.

In Nature of September 1 in your note on the Annual Report on the Royal Botanic Gardens, Trinidad, you emphasize the fact that at Trinidad it always rains with a high barometer.

This is a not uncommon phenomenon in other parts of the world. Last year I made a series of meteorological observations in Mashonaland, and more especially while stopping during June and July at Zimbabwe, and I there found that a high barometer was invariably accompanied by rain, and the higher the barometer the more certain and heavy was the rain. The atmosphere was driest when the barometer was lowest, and then the difference of the readings of the dry and wet bulb thermometers sometimes exceeded 20° F.

This state of climate in Mashonaland is I think mainly due to the configuration of the country, which is such that moisture can only be carried there by southerly and south-easterly winds, and they—as winds blowing towards the equator generally do—increase the atmospheric pressure.

It will be interesting to know if some such explanation will not account for the condition of things in Trinidad, and if any of your readers can tell of a similar state of climate elsewhere.

Robert M. W. Swan.

The Perseids.

With reference to the note, August 18th, that no news of the Perseids had then come to hand, I fancy the shower must have been fairly bright this year. One of our scholars, C. E. Elcock, while crossing from Belfast on the 9th, saw some bright meteors in ten minutes between 9 and 9.30, one lasting some time. Afterwards only occasional ones occurred.

J. Edmund Clark.

Bootham, York, August 29.

Variable Star T Cassiopeiæ.

FROM long-continued observations of the above star, irregularities in the ascending light curve may be expected about October or November next. I shall be happy to supply a diagram of the field to any one interested in the question.

CUTHBERT E. PEEK.

Rousdon Observatory, Lyme, September 5.

THE OPPOSITION OF MARS.

THE *Times* of Saturday contains a most important telegram, giving the results of Prof. Pickering's observations in Peru during the present opposition of Mars, which is one of the most favourable which has occurred during the last half of the present century. The work done at Arequipa in one respect contradicts, and in others goes far beyond, the results recently announced from the Lick Observatory. There can be no doubt that a considerable advance has been made by this year's results; many prior observations which have been considered doubtful have been confirmed, and an additional interest lent to the observation of the planet.

The time, therefore, seems opportune for considering several questions connected with Mars, and it will be convenient to begin with the conditions of this year's observations, especially since the least astronomical among us has certainly noted with surprise the bright red star which now nightly rises low down in the south-east. Nor will he or she be less inclined to regard it when it is recognized as the planet about which during the last month so much has been written of human rather than of astronomical interest. If everything that one sees in print be true, the inhabitants of Mars are signalling to us, and it only remains for us to choose our manner of reply. Of course from signals the imagination of the ready writer has passed at once to words, and having got so far, each planet is about to become acquainted with the history and present conditionings of the other by means of a language understanded of our neighbours as well as ourselves.

But first as to the cause of its excessive brilliancy during the last month or so, for this doubtless has had something to do with the present general interest taken in the planet. Mars was as bright in 1877, but on that occasion nothing like the present amount of interest was taken in its movements and possible structure. For this there are two obvious causes—one the increasing interest taken by people in science generally; the other, popular glosses on several recent discoveries made regarding Mars itself.

The popular idea that the changes which have been recently observed on the planet are changes due to the work of its inhabitants—an idea based upon a mistranslation of a word—has, of course, generated the other one—namely, that vast operations have been undertaken for signalling purposes; and from this idea the step to Mr. Galton's or Mr. Haweis's method of signalling back is a small one. Small though it be, however, the public interest has thereby been greatly enhanced.

One of the most serious suggestions in modern times regarding signalling to bodies outside the earth we owe to a German astronomer, who some while ago enriched the world with the idea that the inhabitants of the Moon might possibly be communicated with by establishing on the vast plains of Siberia geometrical figures, such as circles, &c., built up of fire-signals, to which signal, if seen, the Lunarians would reply by reproducing them.

Then the popular mind was content to bridge the chasm of 240,000 miles which separates us from the moon. But *now* Mars is the objective—Mars, which at its nearest approach is 35,000,000 of miles removed!

…t Mars when in opposition may be very much further away than that; so far, indeed, that it is then observed to be 1-5th of its maximum brightness, and naturally with very reduced angular diameter. The two preceding oppositions at which its brightness has been at all comparable to its present one, took place in 1860 and 1877, so that we find the most favourable oppositions about sixteen years apart. The reason of this will easily be gathered from Fig. 1, which shows with sufficient accuracy the very elliptic orbit of Mars in relation to that of the earth. The lines joining the two orbits are those connecting the two planets during some oppositions from 1830 onwards to 1871. The outer planet, Mars, is represented nearly at the *perihelion* part of its orbit, that is the point at which it is nearest the sun (and therefore the earth, if we treat the earth's orbit as a circle), and the reason that the 1830 and 1862 observing conditions were so much better than those of 1869 and 1871 is at once clear. The opposition of 1877 and the present are not shown on the diagram, but they occurred at a time when Mars was not far from its perihelion.

The diagram also allows us to see that at the perihelion point of Mars' orbit the planet is very nearly at the time of the southern solstice, the N. pole being inclined away from the sun. Also that this must occur about four months before the southern solstice of the earth, the direction of the axis of which is also shown.

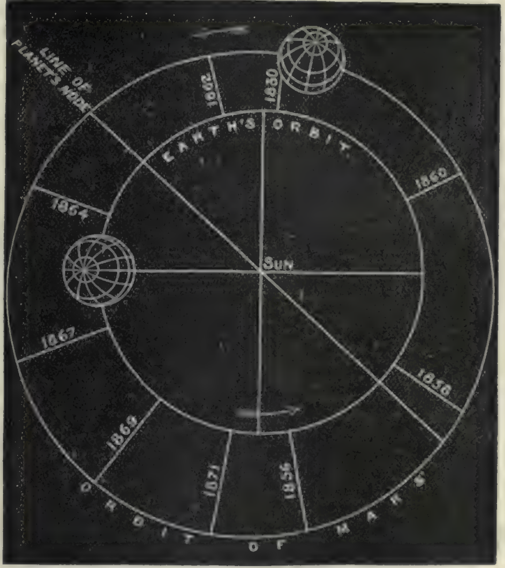

FIG. 1.—The orbits of the Earth and Mars.

So that at an opposition which occurs in August, as the present one does, we observe what happens in the summer solstice of the northern, and winter solstice of the southern, hemisphere of the planet. In fact, generally we have:—

Time of opposition.	N. hemisphere.	S. hemisphere.
August	Winter	Summer
November	Spring	Autumn
February	Summer	Winter
May	Autumn	Spring

The perihelion point of a planet's orbit is astronomically expressed by its heliocentric longitude, and the apparent size of its disc (on which its apparent brightness depends) by its semi-diameter in seconds of arc. Presuming that the longitude of the perihelion of Mars may be taken as about 334°, the following table will show how the great brilliancy of the planet in 1877 and the present year was caused; other less favourable oppositions are given for purposes of comparison:—

Date of opposition.	Semi-diameter.	Heliocentric longitude of planet.
	″	°
1862, October 5	10·8	12
1869, February 13	8·2	145
1873, April 27	9·7	217
1877, September 5... ...	**14·7**	**343**
1881, December 26 ...	9·2	95
1884, January 31	8·3	132
1888, April 10	9·2	201
1892, August 13	**14·7**	**312**

So much, then, for the distance conditions. At its nearest approach the planet is 35,000,000 miles removed—let us say 150 times more distant than the moon.

We next come to the conditions of visibility. Mars is nearest to us (the degree of nearness depending upon its position in its orbit) when "in opposition," as we have said—that is, when it is in the south at midnight, and opposite the sun, the sun then being, of course, due north below the horizon. It will then appear to us "full," as the moon is said to be full when she occupies an analogous position. At this moment, then, the earth is invisible to the inhabitants of Mars unless she happens to transit the sun's disc.

The earth appears to Mars precisely as Venus does to us, and if inhabitants there be on Mars, and they study astronomy, a transit of earth to them will be what a transit of Venus is to us.

Further, as we see Venus as a half-moon, and when nearer to us as a fine large crescent, so the Martians, as the earth approaches them, will see her as a half-moon and then as a crescent, getting finer as the apparent diameter of the completed circle gets greater.

Mars, to see us best, must occupy a point near its perihelion. These things may be gathered from Fig. 2, in which an opposition at Mars' perihelion is shown, the orbits, but not the size of the bodies concerned, being to scale. Before the conjunction of the three bodies (in the line Mars, earth, sun) is approached, Mars will first have the earth as a half-moon at a; this will gradually melt into a crescent till the moment of conjunction. Afterwards the crescent will broaden, and its diameter will be reduced till the point a' is reached, when the earth will appear as a half-moon again.

It is clear, therefore, that the earth will be a morning and evening star to Mars at the time of their nearest approach. The earth's crescent must not be too fine, or no observation will be possible on a dark background of sky. In other words, although we can observe Mars best when he is nearest, the privilege of seeing the earth when nearest to Mars is denied to his inhabitants.

We are now, then, in a position to discuss, so far as the mere conditions of visibility are concerned, the two suggestions as to earth-signalling to which I have already referred.

Mr. Galton's proposal depends upon the observation that a "reflected beam of sunlight sent through a hole in a plate in front of the mirror was just distinctly visible as a faint glint at a distance of ten miles when the hole was a square of one-tenth of an inch in the side." He then adds: "The amount of fog and haze that a beam of light would traverse between us and Mars when the planet was high above our horizon could not exceed that along a terrestrial base of ten miles; consequently the same proportion between the size of mirror and the distance would still hold true. It follows that the flash from many mirrors simultaneously, whose aggregate width was fifteen yards, and whose aggregate length (to allow for slope) was, say, twenty-five yards, would be visible in Mars if seen through a telescope such as that at the Lick Observatory. With funds and good will, there seems no insuperable difficulty in flashing from a very much larger surface than the above, and sending signals that the inhabitants of Mars, if they have eyes, wits, and fairly good telescopes, would speculate on and wish to answer. One, two, three, might be slowly flashed over and over again from us to them, and possibly in some years, to allow time for speculation in Mars to bear practical fruit, one, two, three, might come back in response. Dr. Whewell, if I recollect right, wrote a paper on the possibility of coming to an understanding with lunar inhabitants, if there were any. He would begin from the mathematical side. The practical difficulty is by no means insuperable of enabling many independent observers (who need not be near together) to direct their flashes aright. If mirrors could be mounted without much cost as heliostats (and perhaps they can be) it would be easy enough to do this. My own method is not practicable, at least without considerable addition and modifications, as it requires the object to be visible towards which the flash is directed, but Mars is not visible to the naked eye at day."[1]

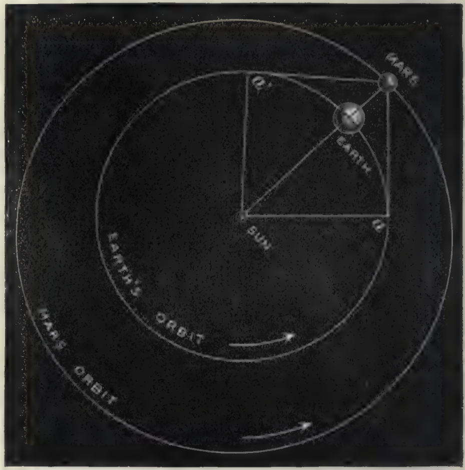

FIG. 2.—The Conditions of Visibility of the Earth from Mars.

Mr. Galton then uses sunlight and works in the day; Mr. Haweis, on the other hand, suggests electricity and night-time:—

"I infer from the astronomers that a signal on our earth about six miles in size of the nature of a bright light could be seen by the inhabitants of Mars, who by all accounts seem to be making the most systematic and herculean efforts to communicate with us by flashing triangular signals of presumably electric light. Why cannot we answer those signals by something which would resemble the lighthouse intermittent signal? Here is the method. London every night presents an area of at least twelve miles square brilliantly illuminated. That illuminating power might be enormously increased with only a few additional centres of powerful electric light. But without *any additional expense*, a little co-operation on the part of the gas companies would suffice to alternate darkness and light at intervals of five minutes over the whole of London between certain hours when traffic is more or less suspended. If only tried for an hour each night some results might be obtained. . . . . We have actually the mechanism for interplanetary communication every night—why not use it ?"[1]

---

[1] *Times*, August 6, 1892.

Mr. Galton is careful to point out that his method of signalling requires sunlight, and that the signals are to be flashed to Mars in the Earth's daytime; the moment of opposition therefore is at once out of the question. Even with the Earth at either *a* or *a'* in our Fig. 2, the Sun and Mars would be 90° apart, and in any case the signals would be visible to the Martians (if visible at all) on the part of the earth lit up by the Sun. This does not seem a favourable condition, or at all events the most favourable one.

Mr. Haweis' plan secures a much stronger contrast. If it or something like it could be carried out, we can imagine the inhabitants of Mars studying the delicate earth crescent (with telescopes as powerful or more powerful than our own *bien entendu*), whether as a morning or evening star, and then seeing rhythmic flashes, reproducing the star included in the crescent of the Ottoman flag well within the horns of the crescent. Here we certainly get light on dark instead of light on light.

But there are other conditions of visibility besides those we have so far discussed. Supposing the whole electric energy of London turned on Mars would the volume of light be sufficient to produce a valid signal?

It is worth while, quite independently of the popular expectations of the present moment, to inquire into the actual conditions of the problem, telescopes on Mars as powerful as our own being always assumed.

If we are armed with a powerful telescope, under the best seeing conditions, first among which is its location at a considerable elevation, we may perhaps reckon upon using a power of 1000, that is, the object is magnified a thousand diameters; in other words, it is brought a thousand times nearer. In the case of the moon, under these conditions any part of her we might choose to study could be examined, as if from London we were viewing it over Yorkshire with the naked eye.

The late Mr. Lassell, I believe, claimed as the highest achievement possible with his 4-foot telescope in the pure air of Malta, that if the lunarians were shaking a carpet as large as Lincoln's Inn Fields he could see whether it was round or square. This then would be the *ne plus ultra* in the case of a body 240,000 miles away.

Now, if we take the nearest distance to Mars as 35,000,000 miles, as I have stated,

			Miles.	
1,000,000	magnifying power would give us the power of studying Mars as if it were		35	away from us.
100,000	ditto	ditto	350	
10,000	ditto	ditto	3500	
1000	ditto	ditto	35,000	

We can put this differently. To the naked eye at the distance of Mars $1'' = 160$ miles. Were Mars 1000 times nearer $1''$ would become ·16 mile. Now this at first seems very hopeful, for the exterior satellite of Mars has been seen in various telescopes.

We have already learned that the power employed last month at the Lick Observatory has not been so much as 1000, but such that the planet has been brought within a distance of 50,000 miles. Under these conditions a line on Mars a quarter of a mile long will subtend an angle of $1''$, or two lines a quarter of a mile apart should be separated and appear as doubles.

The second satellite to which reference has been made is only some 10 miles in diameter. We are justified by the visibility of the satellite, then, in saying that if a space 10 miles in diameter could be lighted up, as brilliantly as by sunlight, on the dark hemisphere of the Earth when Mars is above the horizon and at perihelion, it could be seen from Mars by telescopes equal to our own.

London, of course, is more than 10 miles in diameter, and we can imagine all the navies of the world with their search lights to flash simultaneously towards the planet, or to light up the clouds in a space as large as London, but there then will remain the question of the intensity of the light. What do electricians say is possible in this direction?

Whatever the answer to this question may be, it seems that signalling on Mr. Haweis' lines, light on dark, is a more hopeful proceeding than that suggested by Mr. Galton, and that on this system our conditions for reading signals are far better than those on Mars, as our dark hemisphere is much more exposed to our sister planet than is hers to us.

It is time now that we turn to those recent observations of our neighbour which have given rise to the ideas we have been discussing—ideas based upon the supposition that there is evidence which goes to show that the Martians are signalling to us by digging "canals" 1000 miles long and 200 miles wide, and then doubling them, and in addition lighting numerous signal fires or flashing electric lights!

Here we approach a region of astronomical inquiry which requires no enhancement of its interest by the intrusion of popular delusions or imaginings, which, moreover, for the next few months as details come to hand, will have all eyes directed to it.

It is not necessary to go further back than the year 1830 to appreciate the importance of the later inquiries. In 1830 Beer and Mädler made an admirable series of drawings of the planet which enabled them to affirm the existence of fixed markings, and having fixed markings, not a long series of observations was necessary to determine the period of the planet's rotation on its axis.

In 1862 I (and many others) had no difficulty in recognizing the features on the planet which Beer and Mädler had observed with smaller optical power thirty years before. The instrument employed was a 6-inch Cooke achromatic, which I still hold to be one of the finest telescopes ever made. It enabled me to add details to those before noted, and the observations left no doubt on my mind that Mars had an atmosphere like our own; that its temperature did not vary many degrees from our own; that there were land surfaces and water surfaces; clouds and very obvious cloud drift; polar snows which melted with marvellous rapidity as the perihelion sun made its full strength felt. Further, that the changes in the appearances observed, especially in the lighter or darker shading, depended upon clouds and the smoothness or roughness of the water surfaces.

This latter conclusion I arrived at from the fact that the darkest markings, assuming them to be water surfaces, were more or less land-locked, and that changes in some of these surfaces were always most obvious close to the land. It was clear also that the rapid melting of the polar snow must be accompanied by tremendous inundations.

I append, as an example of the kind of work done on the planet with the small refractors generally available thirty years ago, some extracts from a memoir I communicated to the Astronomical Society at that time.[1] The large refractors employed added so far as I know very little.

> "Although the complete fixity of the main features of the planet has been thus placed beyond all doubt, daily—nay, *hourly*—changes in the detail and in the tones of the different parts of the planet, both light and dark, occur. These changes are, I doubt not, caused by the transit of clouds over the different

---

[1] *Pall Mall Gazette*, August 18.

[1] Mem. R.A.S. 1863, p. 179.

features. The effect of a cloudless and perfectly pure sky, both here and on Mars, appears to be that the dark portions of the planet become darkest and most distinctly visible; the coast-lines (if I may so call them) being at such times so hard and sharp, that (as has been mentioned by Mr. Lassell) it is quite impossible to represent the outlines faithfully; and this effect, be it observed, is completely distinct from the way in which the features grow upon one. MM. Beer and Mädler remark: 'Generally some time elapsed before the undefined mass of spots seen upon first looking into the telescope resolved itself into recognizable parts.' This observation will commend itself to all who have observed such a delicate object.

"The effect of clouds, on the contrary, will be, I think, to make the *dark portions less dark* in proportion to the density of the clouds, and the *light portions lighter* in the same proportion. *It can never make a light portion dark.* If this be so, when we see a dark spot well defined, we can be sure that no clouds are above it, and that we actually see the planet itself; we cannot be sure, however (unless we are acquainted with the locality from previous observation), that dark spots do not underlie any of the lighter portions. Some instances of cloud-transit were suspected by Father Secchi in 1858. Several unmistakable instances occurred during my observations. . . .

"But besides the cloud-masses, which, as we have seen, obliterate the dark portions either partly or wholly, giving rise to different contours and tones, and rendering the actual features of the planet undistinguishable, the dense atmosphere of Mars, with its fogs and mists, appears to go for very much. I mention this more especially to point out that—although its effect was evident in the southern hemisphere in mid-summer, upon the spots as they came on, and left the disc, as remarked by previous observers—it was much more evident in the northern hemisphere in mid-winter, blotting out, as before remarked, *even on the central meridian*, all features north of + 30° latitude. This would appear to furnish another proof of extreme seasons on Mars, in addition to that supplied by the rapid melting and great extent of the polar snows, and to point out the desirability of taking advantage of all oppositions which happen, as did those last year and in 1830, in the full summer-time of the southern hemisphere, when the atmospheric conditions of the planet may be considered the best possible. With regard to this last point, it may be remarked that the southern hemisphere is the one which we shall ever be able to study best, in consequence of the great distance of the planet from us at those oppositions which occur when the northern one is turned to us.

"With regard to the green and red tints so often noticed on Mars, my observations have led me to hold the same opinions as to their nature as those arrived at by Father Secchi in his study of the planet in 1858. Nor do I think that it can any longer be doubted that—as he considered probable—the green and red portions do actually represent seas and continents, and are not the effect of contrast.

"The dark portions were noticed to be decidedly green in my instrument, both by myself and others who observed Mars from time to time with me, the colour being especially marked in Beer and Mädler's spot *p n* (Drawings Nos. 7 and 8). In spite of the over-correction of my object-glass, which should have 'reinforced' the red tinge, it was never sufficiently decided, I think, to suggest a contrast; and, indeed, the green was sometimes unmistakable when the red was not noticed, and when therefore there was no contrast to mislead the eye.

"Another point of agreement between the two series of drawings is not a little remarkable: the spots which were observed to be of a most decidedly dark tint in 1830 were darkest last year; and supposing the dark portions to be water, the darkest spots are those which are nearly, if not quite, land-locked. Passing on from the consideration of the general features of the planet, the snow-zone next demands our attention. . . . . Last year the solstice occurred on August 30, on the 23rd of which month the snow-zone was estimated to be $\frac{1}{6}$ of the apparent diameter; by the 25th of the next month, September, this was reduced to about $\frac{1}{10}$, and again to $\frac{1}{13}$ by October 11, when it was at times scarcely discernible; after which it began apparently to increase again.

"To the great eccentricity of the orbit of Mars, and the fact that the summer of the southern hemisphere occurs when the planet is near perihelion, is doubtless to be ascribed this very rapid melting of the southern snow-zone, an observation confirmed by the much slighter variation in the dimensions of the opposite one. It appears to follow from my drawings, and I think also from those of Messrs. Beer and Mädler, although they make no mention of the fact, that even at its minimum the centre of the snow-zone was not absolutely coincident with the planet's pole, being situated in somewhere about 20° of areocentric longitude (using Beer and Mädler's start-point), and in a latitude probably only a very few degrees from it. . . . . The snow-zone was at times so bright that, like the crescent of the young moon, it appeared to project beyond the planet's limb. This effect of irradiation was frequently visible; on one occasion the snow-spot was observed to shine like a nebulous star when the planet itself was obscured by clouds, a phenomenon noticed by Messrs. Beer and Mädler, recorded in their valuable work, *Fragments sur les Corps Célestes.* The brightness, however, seemed to vary very considerably, and at times, especially when the snow-zone was near its minimum, it was by no means the prominent object it generally is upon the planet's disc."

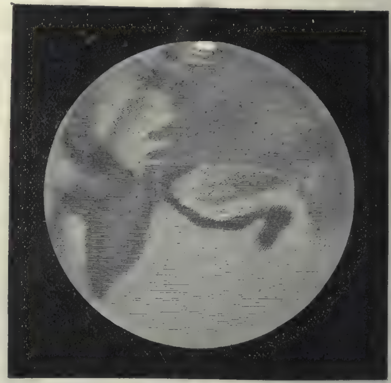

FIG. 3. Mars September 25, 1863, showing the darker shading of a land-locked water surface and its projection into the open water beyond.

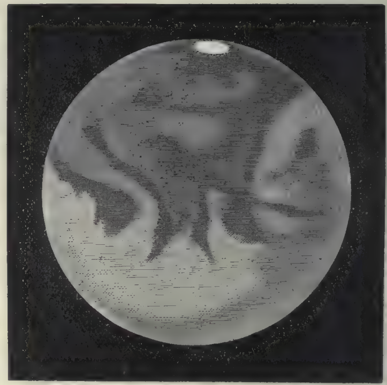

FIG. 4. Mars September 23, 1862, showing bright appearance of snow cap, and the details of one of the chief coast lines.

We owe it to the illustrious Italian astronomer Schiaparelli that a world of wonders undreamt of thirty years ago now forms the chief subject of inquiry. His work was begun at the opposition of 1877, which, as we have seen, was as favourable as the present one, and continued during that of 1879-80. He showed that those parts of the planet which had been regarded by myself and others as the land surfaces, instead of being wanting in detail, as they had been seen, were really riddled by streaks, many of them very long and very straight, but in every case running towards a water surface, and in many cases connecting two water surfaces. These streaks he called *canali*, which in Italian, as *canalis* in Latin, means either a channel, a canal, or a pipe. Unfortunately, however, whenever it has been translated into English the word *canal* has been used, which of course with us suggests human labour. We have already seen what this has led to.

As a result of this minute inquiry rendered possible by his fine instrument (8¾ in. Merz) and perfect observing weather, a complete map of the planet with these channels was made.[1] But this was but the beginning of marvels. During the opposition of 1881-82 the work was continued, and now Schiaparelli, besides endorsing all the discoveries of 1880-81, found that in at least twenty cases the channels were doubled and consisted of two streaks 200 or 400 miles apart, instead of one. I append a copy of the sketch map he gave in his preliminary communication to the Academy of the Lincei.[2]

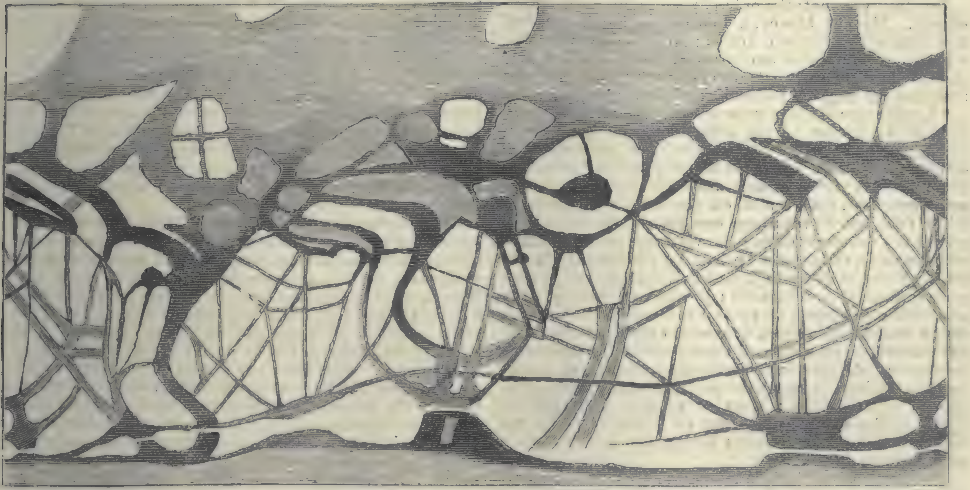

FIG. 5. Doubling of the channels, observed by Schiaparelli in 1882.

He distinctly stated that the doubling of these channels seemed to be connected with the time of the planet's year, and to occur simultaneously over the superficies of the planet which is supposed to represent land. When the opposition took place in August, that is in the full winter of the northern hemisphere, no trace of the doubling was visible which is precisely what we should expect if the doubling depended in any way upon inundations caused by the melting of the northern snows, the north pole being turned away from the sun. The vernal equinox took place on December 18, 1881, and the opposition took place in the same month. The doubling of 17 of these channels was observed between January 19 and February 19—that is, in the late spring of the northern hemisphere, which again is precisely what we should expect if they were connected with inundations.

Not only was this wonderful change noted, but here and there bright spots (previously noted by Green in 1877, and recalling Dawes' "snow island," seen in 1865), were recorded.

In the doubling of these water channels then, and in these snow-tipped hills, we have the origin of the "canal digging" and "fire signals" of which we have lately heard so much.

It will thus be seen that the widespread notions of the signals from Mars rest only on a mistranslation and upon the popular imagination running riot among the startling revelations of modern observers, among whom in this special line of work Schiaparelli must be acknowledged as *facile princeps*.

The observations which engendered invention in one class of minds engendered doubts in others, but the work of Perrotin and Thollon at Nice in 1886 with the 15-inch refractor has completely endorsed the main points advanced by Schiaparelli with regard to the existence of the channels or straits. Two or three references to their published papers will show clearly what their view of the relation of them to the variously-tinted parts of the planet really is:—

"The triangular continent, somewhat larger than France (the Lybia of Schiaparelli's map), which at that time stretched along both sides of the equator, and which was bounded south and west by a sea, north and east by channels, has disappeared. The place where it stood, as indicated by the reddish-white tint of land, now shows the black, or rather deep-blue, colour of the seas of Mars. The Lake Mœris, situated on one of the channels, has also vanished, and a new channel, about 20° long and 1° or 1°·5 broad, is now visible, running parallel with the equator to the north of the vanished continent. This channel forms a direct continuation of a previously existing double channel, which it now connects with the sea. Another change is the unexpected appearance about the north pole of another passage, which seems to connect two neighbouring seas through the polar ice."[1]

A short time afterwards M. Perrotin stated that this same district of Libya, had undergone a further change, the "sea" which had so recently covered it having retreated again for the most part, so that the appearance of the district was intermediate between that which it recently presented and that under which it was seen in 1886. Of the channels M. Perrotin has noticed four, three of which are double, which, starting from the "seas" of the southern hemisphere near the equator, and following a nearly meridional course, extend right up to the north polar ice cap, being traceable across the "seas" which immediately surround the latter.

[1] Abstract in NATURE May 21, 1888.

Although Schiaparelli, as it will have been seen, connects the changes in the channels with the seasons of Mars, and although Perrotin and Thollon show their relation to the seas in their vicinity, other explanations of the phenomena have been suggested. Among these we must first refer to the view of Fizeau,[1] that we were in presence of the results of glaciation on a tremendous scale, the parallel ridges being likened to crevasses or rectilinear fissures! It was imagined by him that relatively longer seasons and a lower temperature were capable of producing crevasses some thousands of miles long and hundreds broad.

But this was not the only physiographic explanation offered. Mayeul Lamey, a Benedictine monk, ascribed the channels to volcanic action; to him they were the remains of enormous crater walls, and he states that they are best seen when Mars reaches its most gibbous form and the angle of the incident light is greatest.

"Le plus souvent les astronomes se bornent à observer Mars vers l'époque de son opposition, c'est-à-dire de sa plus grande proximité de la terre; c'est, pensent-ils, le meilleur moyen de voir bien et de près les 'mers' de Mars. Si ces taches étaient des mers la raisonnement serait excellent, mais il n'en est pas ainsi. M. Schiaparelli a déjà fait la remarque que les canaux découverts par lui ont été observés non au voisinage de l'opposition mais un mois, deux mois après. Et pourtant la planète est alors bien eloignée déjà de nous. Pour moi, je constate également le même fait; je découvre tous les soirs un nombre de cirques de plus en plus considérable. La raison en est bien simple, du moment que les taches sont des ombres, ou du moins des parties réfléchissant moins lu lumière. A l'époque de l'opposition, en effet, les rayons solaires tombent à peu près perpendiculairement sur la surface de la planète; Mars ne possède alors pas de phase, tandis qu'un mois avant ou après, la phase est très accentuée et les ombres deviennent possibles avec les élévations du sol."[2]

Another attempted explanation was that the channels were doubled in consequence of some play of diffraction. But enough has been said on this head; let us rather turn to the first fruits of last month's work.

At the Lick Observatory the channels were seen, and one of them was considered by three observers to be doubled.

From Peru we learn that Prof. Pickering saw many of the channels observed by Schiaparelli, but all were found to be single. The telegram adds, "not double, as stated by him"; but here is an error. We are near the southern solstice, as in 1877, and they were *not* seen double at that epoch. But even this is comparatively uninteresting after the revelations as to the effects of the melting snows.

Prof. Pickering discovered two mountain ranges in Mars to the north of the green patch near the planet's south pole. Between these mountain ranges the melted snow has collected before flowing northward. In the equatorial mountain regions snow fell, covering two of the summits, on August 5. On August 7 the snow had melted. "I have seen eleven lakes," the professor writes, "varying in size. These lakes branched out in dark lines connecting them with two large dark areas like seas, but not blue. There has been much local disturbance in the clouds round the planet since the snow melted, as is evident from the dense clouds which were concentrated within one area. These clouds were not white, but yellowish in colour, and partly transparent. They now seem to be breaking up, but are still hanging densely on the south side of the mountain range. The northern green spot has been photographed."

Surely we have here the connection between the work of 1862 and 1877. The channels are true water channels; at one time at low channel we may have an unimportant stream like the low Nile; at another an ancient river-bed as it were, is filled to the utmost limit by the inundation. One requires to have seen an Indian river, or better still, the Nile valley to realize what an inundation may mean, and especially under the conditions which have now been established to exist on Mars. But we may go further. A comparison of Schiaparelli's sketch of 1882 with his map of 1879, helps us considerably, and shows that we must take the effect of clouds over warm water into consideration. Two among the most undoubted and continuous water-surfaces which I observed in 1862, which he has named Mare Cimmerium and Sabæus Sinus, were doubled also in 1882, and in my mind there is no doubt whatever that this doubling, at all events, is due to cloud banks lying, or rather travelling longitudinally, along the centre of the water-surface, precisely as the most magnificent cumuli which I have seen on this planet, follow the Equatorial current, entering the Carribean Sea by Tobago. Obviously, by their lightness of shade, the channels are shallow, and they are only noticed in or near the tropics, so that the water must be highly heated before it empties itself into any of the southern seas.

Certainly it must be acknowledged that while the revelations show a remarkable similarity to our own atmosphere, so far as chemical structure and temperature are concerned, for the *onus probandi* lies with those who deny that we are dealing with the various forms of water, it would appear that the extremes of heat and cold are more generally operative in Mars than with us. The problem thus presented to us should prove interesting to the geologist. Was there any period in the earth's past history, or can there be in the future, which more resembles the present Martian conditions? Had we these enormous inundations, chiefly caused by polar snows melting? If not, were we sheltered from them by our more circular orbit and shorter year? Is Mars red because it is muddy? If so, what mud could give it the tinge we know?

J. NORMAN LOCKYER.

NOTES.

FOR some days much anxiety was felt as to the condition of Sir Richard Owen. We are glad to say that his health has greatly improved, and that he is now able to take more nourishment.

THE four hundredth anniversary of the discovery of America is being celebrated this week with great splendour at Genoa. The King and Queen of Italy are taking part in the celebration, and the maritime Powers are represented by a fine assemblage of warships.

A BOTANICAL CONGRESS, which is attended by some of the most eminent botanists of Berlin, Paris, Jena, and St. Petersburg, was opened at the University of Genoa on September 5.

AN interesting ceremony took place at the University of Genoa on Tuesday, when the Hanbury Institute was formally handed over to that body. The correspondent of the *Times* at Genoa says that Mr. Thomas Hanbury, an English gentleman, whose house at La Martola, near Ventimiglia, is well known to visitors to the Riviera, had already won the gratitude of Italians by his generous deeds in that neighbourhood, and a year or two ago he offered £4000 to found an institution in Genoa for the encouragement of the study of botany. Senator Secondi, president of the University, gave expression to a sincere feeling of gratitude towards Mr. Hanbury, and accepted the gift of the institute in the name of the University. A large number of distinguished botanists, who are attending the congress now being held there, were present at the ceremony.

[2] "Note sur la Découverte du Système Géologique Éruptif de la planète Mars." Par Fr. Mayeul Lamay, O.S.B. Autun. (Dejussien, 1884.)

THE meeting of the German Mathematicians' Union in Nürnberg, and the Mathematical Exhibition, are postponed on account of the cholera.

THE German Chemical Society have resolved to found an Institute in remembrance of the late Prof. von Hofmann. Large funds will naturally be required, and all pupils and those who honour Hofmann's life and work are earnestly requested, in a recently-issued circular, to send contributions. Even those who had no personal knowledge of the illustrious *savant*, but have been inspired to work by his example, will no doubt be willing to take part in the scheme. The proposed Institute will not merely serve chemical purposes, but will be a place of general scientific research.

THE International Congress of Physiologists has held its second triennial session at Liège with Prof. Holmgren (Upsala) as President, in the Physiological Institute under Prof. Léon Fredericq. The Congress terminated on Thursday, September 1, after a banquet at which the Burgomaster of the city was present. More than one hundred physiologists attended the Congress.

THE thirteenth Congress of the Sanitary Institute will be held at Portsmouth from September 12 to 17. Sir Charles Cameron will preside. The Congress will be divided into three sections—one dealing with sanitary science and preventive medicine, another with engineering and architecture, and a third with chemistry, meteorology, and geology. Conferences will be held by naval and military hygienists, by medical officers of health, by municipal and county engineers and surveyors, by sanitary inspectors, and by ladies on domestic hygiene. A health exhibition, including sanitary apparatus and appliances, in connection with the Congress, will be held in the Drill Hall from September 12 to October 8.

A PHOTOGRAPH of the late Admiral Mouchez—one of the best photographs of him we have seen—appears in the July number of the *Bulletin Astronomique*, which journal owes its existence to his indefatigable exertions. There is also a brief account of his life written by M. Tisserand.

THE sixth session of the Vacation Courses, known as the Edinburgh Summer Meeting, has just come to a close after a very successful month's work. The importance of this meeting increases year by year with the steadily increasing number of students, and with the more complete organization of the plan of study. This has again been arranged so as to assist in the training of school teachers and University Extension lecturers for the new duties which are beginning to devolve upon them in connection with the requirements of County Councils for technical education. Hence the principle of "Regional Study" has again been kept prominently in view, Edinburgh and its districts being taken as a typical area, and affording a starting point and vivid concrete illustrations for the courses on sociology and anthropology (Profs. Geddes and Haddon) on the one hand, and on the other for those on biology (with special courses of zoology and botany) and physiology by Mr. J. Arthur Thomson, Prof. Haycraft, and others. The course on literature by Prof. Moulton, which was very largely attended, followed to a large extent the same general lines as the more purely scientific courses. The work in the historical seminary and the studio was continued, and a series of technical education lectures was given in the evenings by Principal Dyer, Profs. Mavor, Geddes, and Prince, Mr. C. Williams, and others. Many nationalities were represented among both students and teachers. Besides many British Association and other visitors, Profs. Haeckel (Jena), Delage (Paris), attended the meeting. Special lectures were delivered by Profs. Devine and Rolf (Philadelphia), Profs. Manouvrier and Demoulins (Paris), Principal Dyer, Profs. Mavor, Prince, Lloyd Morgan, Sollas, Messrs. R. Aitken, W. Renton, R. Irvine, and others. A series of interpretative recitals by Prof. Moulton, and four concerts illustrating the history of music were also given.

FIFTY scholarships, named the Townshend Scholarships, from funds bequeathed by the late Rev. Chauncey Hare Townshend, for working-class boys or girls between 14 and 21, to be held for one year, have just been established in connection with the Westminster Technical Institute, 40 being free and 10 competitive. The subjects taught in the Institute, which was founded by the Baroness Burdett-Coutts, are rudimentary, commercial, and technical, and include drawing, technical, mechanical, and artistic; geometry, practical, plane, and solid; working in wood, lead, metal-plate, &c.; cookery, dressmaking, shorthand, foreign languages, &c.

A REMARKABLE grotto, which is exciting the interest of French geologists and mining engineers, was recently revealed by an explosion during the progress of the ordinary work in a quarry at Taverny. The Paris correspondent of the *Times* says there is a subterranean gallery, with walls polished as if by water; and that it is some 1500 feet in length, and ends in a great chamber about 40 feet in diameter and 6 feet in height. Scientific men have hazarded various conjectures as to the source of the watercourse by which this cavity seems to have been formed.

MR. HERMANN KRONE gives, in No. 7 of Wiedemann's "Annalen," an account of some further experiments connected with the photography of spectra in their natural colours by Lippmann's method. He finds that the correct rendering of the various colours depends upon a high degree of accuracy in the proportions of the finely divided silver haloid and the colour sensitiser, as also upon the temperature of drying, the exposure, and the development. If the essential conditions are not fulfilled, it may happen that yellow appears in the place of red, or that green exhibits a direct transition into violet, the blue being unrepresented. The result also depends upon the amount of water contained in the film, as influencing its thickness, and in the case of the solar spectrum upon the altitude of the sun. With a very long exposure the infra-red appears as a dark purple, and the ultra-violet as a yellowish-pink lavender colour. Mr. Krone has also succeeded in producing coloured photographs without Lippmann's mercury mirror. He simply covers the film with black velvet, exposing, as Lippmann did, through the glass. In this case, the reflection from the inner surfaces of the glass takes the place of that from the mercury. The exposure has to be considerably prolonged, and the colours towards the red end are less pure; but the blue, violet, and ultra-violet are quite as brilliant and well defined as in the mercury process.

DURING the past week the weather has assumed a decidedly autumnal character, the maximum temperatures being below 65° in many parts of the United Kingdom, and below 55° in some of the northern parts. For the first few days depressions from the Atlantic caused unsettled and showery weather, with strong winds or gales. On Sunday, however, an area of high pressure spread over England, and under its influence the sky rapidly cleared, and the wind became northerly, while at Greenwich Observatory a temperature of 4° below freezing point was registered on the grass; but the more northern and western parts of the Kingdom were still disturbed by depressions from the westward. These have subsequently spread over the greater part of the country, and winds have again become south-westerly generally. The facts shown by the *Weekly Weather Report* for the period ending the 3rd instant, are interesting:—The rainfall exceeded the mean in all districts, the greatest excess being in the west of Scotland and the north-west of England, and the fall was more than twice as much as the normal amount over the Kingdom generally. Temperature was below the mean in all districts, except the south of England and the Channel Islands, while in Scotland the lowest shade minima were between 32° and 35°.

PROF. MOHOROVIÉIÉ, of Agram, writes to the *Meteorologische Zeitschrift* for August a preliminary notice of a most destructive wind-rush, which occurred at Novska, in Slavonia, on May 31 last, and which he has been requested by the government to investigate on the spot. He reports that as the train left Novska station soon after 4 p.m. on that day, a sudden darkness came on; all the carriages of the train were thrown off the line with a great crash, and three of them were carried by the force of the wind to a distance of about 100 feet, the violence of the wind being aided by the bursting of two water-spouts over the railway. The tornado then traversed a primeval forest which lies to the north-east of Novska, tearing up over 150,000 large trees, and stretching them on the ground round the centre of the disturbance with the regularity of arrows around a barometric minimum of a weather chart, in a lane of about 1½ to 2 miles in diameter. Among the curious instances is one of a girl, seventeen years old, being carried unhurt for a distance of over 300 feet. Were it not for the trustworthy source whence this information is obtained we should consider it to be greatly exaggerated, but Prof. Mohoroviéié states he crossed the forest three times and carefully noted the position of the fallen trees, and he will no doubt give an official report of the occurrence later on, accompanied by meteorological data from various stations.

IN vol. xiv. of *Aus dem Archiv der Deutschen Seewarte* there is a discussion by E. Herrmann on the storms of the German coast in the years 1878–1887, based upon an examination of the observations taken at forty-seven stations, and containing monthly and yearly charts showing the prevalence of the winds from the various points of the compass. The results show a great preponderance of storms in the Baltic as compared with the North Sea; in ten years 191 storms are recorded in the Baltic and 101 in the North Sea. The decrease of storms in the North Sea in summer is also much more marked than in the Baltic. The maximum of westerly storms occurs in December, and that of the easterly storms in March and April. In the summer months most storms occur in August. The change of direction of the storms from south-west to north-west occurs most frequently in February, March, October, and November; and from north-west to south-west in January, February, and October.

IN a recent valuable memoir to the Berlin Academy on Thermodynamics of the Atmosphere (fourth of a series), Prof. von Bezold considers the cases of supersaturation with vapour, and of "overcooling" (regarding the latter it may be stated that clouds have been observed at a temperature below freezing, but having no ice-particles,—purely water clouds). A sudden cessation of these states, he shows, must result in rapid rise of air-pressure, which is generally of short duration, unless conditions are present which prevent its descent again. As such variations of pressure are characteristic of thunderstorms, the author goes on to investigate the *rôle* of supersaturation and overcoolings in these phenomena, and he shows how various movements and changes in form of thunderclouds, and the origin of hail and other phenomena, may be explained by them. He is of opinion that much thunderstorm rain has, high up, the form of hail or sleet, and the large drops are simply melted hail or sleet particles, these forms playing a more important part in thunderstorms than is commonly supposed.

A REUTER'S telegram from Catania, dated September 2, announced that the eruption of Etna had broken out afresh, and that the chestnut woods on the mountain slopes were being devastated by the lava, which was pouring down the mountain in one dense mass, instead of flowing in two separate streams, as it did before.

THE Norfolk and Norwich Naturalists' Society has issued its Transactions for 1891-92. We are glad to see that this Society, which has now entered upon its 24th year, continues to prosper, the roll of members numbering 250, and the balance-sheet being very satisfactory. The catalogue of the library, which is printed in the current number of the Transactions, occupies 43 pages. Dr. Wheeler, in his presidential address, discourses on the changes which have taken place in recent times in the distribution of some species of insects, more especially of the typical insect fauna of the old fen-land of Huntingdonshire and Cambridgeshire and of the Norfolk Broads. Dr. Plowright contributes a paper on "Neolithic Man in West Norfolk," with illustrations, by Mr. Worthington Smith, of a number of flint implements found on Massingham Heath, near Lynn, and a description of the site of an ancient British village in the same locality. This is followed by a paper on the St. Helen's Swan Pit, in Norwich, where, towards the end of August, from 80 to 100 cygnets may yearly be found gathered together for the purpose of being fatted for the table. Mr. Southwell, the writer of the paper, also gives some interesting particulars of the breeding of the Mute Swans, which abound on the Norfolk waters. Mr. Clement Reid follows with a paper "On the Natural History of Isolated Ponds," as illustrating the dispersal of the fauna and flora of a district in recent times; and Mr. O. V. Aplin contributes a paper "On the Distribution in Great Britain and Ireland of the Red-backed Shrike." This is followed by the eleventh annual report on the Herring Fishery of Yarmouth and Lowestoft, by which it appears that the enormous number of 290,650,800 of these fish were landed at those ports in 1891. There are other minor papers "On the Meteorological Features of 1891," by Mr. Preston, and shorter notes on the "Marine Fishes of Yarmouth," the "Botanical Occurrences of the Past Year," and other matters of interest.

ACCORDING to a report compiled by the French Statistical Bureau, the vineyards of Europe cover 22,973,902 acres. Italy comes first with 8,575,000 acres, followed by France with 4,592,500, Spain with 4,012,500, Austria and Hungary with 1,637,500, and Germany with 300,000 acres. The annual average production of the European vineyards is put at 2,652,300,000 gallons; Italy producing (in round figures) 697,000,000 gallons, France and Spain 608,000,000 each, Austria-Hungary 208,000,000, and Germany 51,000,000 gallons. Spain exports most wine (200,000,000 gallons), but it is chiefly common wine, and it is estimated at only £12,000,000, while the value of the 56,000,000 gallons exported from France is put at nearly as much. Italy comes third with exports of 45,000,000 gallons, estimated at £2,800,000, while Austria and Hungary exported only 16,500,000 gallons worth £1,720,000.

THE American journal *Electricity* notes that Prof. Elisha Gray, Chairman of the World's Congress Committee on an Electrical Congress, has returned to America from Europe. He visited England, France, Germany, Austria, Roumania, Turkey, Italy, Greece, and found everywhere that a lively interest was taken in the Columbian Exhibition. In an interview in the daily press he says, "Many eminent electricians of different countries are expected to attend the congress, including a large number from Great Britain. The work of the World's Congress auxiliary has been done so quietly that the general public is not aware of its extent and efficiency. There seems now to be no question that the World's Congress of 1893 will be very much more largely attended and will be conducted on a more imposing scale than those of any previous occasion in the world's history."

A MODEL of ocean currents is to be shown at the Chicago Exhibition. The surface of the earth is represented on "a huge scientific tank" by an area of about 30 feet square, the ocean and seas being shown by actual water. Small streams of water are ejected through pipes under the model so that the whole body of water moves exactly as the ocean currents move. The direction of the currents is shown distinctly by a white powder on the surface of the water. Near the model will be placed a large map giving details as to the force, volume, and direction of the various ocean currents.

A USEFUL catalogue of Michigan plants, prepared for the thirteenth annual report of the Secretary of the Michigan Board of Agriculture, has been issued separately. It has been drawn up by W. J. Beal and C. F. Wheeler. It is based on a "Catalogue of the Phænogamous and Vascular Cryptogamous Plants of Michigan, Indigenous, Naturalized, and Adventive," by C. F. Wheeler and E. F. Smith. The compilers hope that the publication of their list will stimulate local observers and collectors to do what they can to add to what is known about the plants of Michigan, especially in the matter of geographical distribution.

DR. R. W. SHUFELDT contributes to the Proceedings of the U.S. National Museum (vol. xv., pp. 29–31) a short but interesting paper on "A Maid of Wolpai"—a girl of about fifteen years of age, belonging to the pueblo of Wolpai in north-western Arizona. A portrait of her accompanies the paper. The writer's object is not so much to talk about this particular girl, as to describe the life of a Wolpai woman at the various stages of her career. His conclusion is that, upon the whole, it is by no means an unhappy life. "From her babyhood to maturity," he says, "it is filled in with many pleasurable chapters, and no doubt a great deal of this is due to their contented dispositions, their love of home, and their untiring industry."

IN another paper contributed to the same volume (pp. 279–282) Dr. Shufeldt discusses the evolution of house building among the Navajo Indians. From November, 1884, to the early spring of 1889 Dr. Shufeldt lived at Fort Wingate, a military station in north-western New Mexico, and during the early part of this period there was always to be found a floating population of Navajos living on the outskirts of the fort. He had thus many opportunities of studying their various arts and industries. He shows that contact with the civilization of the white man has led these Indians to improve their plans of house building, and has had "the effect of bringing about an evolution of the same."

A VERY original mode of treatment of some nervous complaints has been recently developed by Dr. Charcot, at the Salpêtrière, in Paris (*La Nature*). He was led to it by observing that patients afflicted with *paralysis agitans*, or shaking palsy, often seemed greatly relieved after long journeys by rail or carriage. The greater the train speed and oscillation, the rougher the road and the shaking, the more they liked it and were benefited. Dr. Charcot, taking up the idea, had a chair made, to which a rapid movement from side to side was imparted by electrical agency; like what one sees in processes of sifting by machinery. To a healthy person the experience is execrable; he very soon seeks relief. Not so the patient, however; he enjoys the shaking, and after a quarter of an hour of it, is another man. He stretches his limbs, loses fatigue, and enjoys a good night's sleep afterwards. There are various other nervous diseases to which the method applies. Certain physicians, indeed, have before used such things as tuning-forks and vibrating rods in treatment of neuralgia, &c. A student of Dr. Charcot, Dr. Gilles de la Tourette, has had a vibrating helmet constructed for nervous headaches. It is applied to the head by means of a number of steel strips. Above is a small electric motor making 600 turns a minute; and at each turn a uniform vibration is imparted to the metallic strips, and so to the head. The sensation is not unpleasant; it induces lassitude and sleepiness.

ON Friday last Prof. R. L. Gardner, of Virginia, addressed the Balloon Society of Great Britain on his researches relating to what he calls the speech of monkeys. He defined speech as that form of materialized thought which was restricted to such sounds as were designed to convey a definite idea from mind to mind. It was, therefore, only one mode of expressing thought; and to come within the limits of speech the sounds must be voluntary, have fixed values, and be intended to suggest to another mind a certain idea or group of ideas more or less complete. Not only did these marks characterize the sounds of monkeys as speech, but, in addition, the sounds were always addressed to certain individuals, with the evident purpose of being understood. Monkeys usually looked at the individual addressed and did not utter these sounds when alone or as a mere pastime. They understood and acted in accordance with the sounds when imitated by the phonograph or other mechanical means, and this indicated that they were guided by sounds alone, and not by signs, gestures, or a physical influence. He had also discovered that some monkeys could count three and had favourite colours, but he did not think they had names for them. He had for hours together watched monkeys convey to each other by sound the apprehension of danger and other emotions. His task, which was not easy, was to perpetuate or imitate these sounds. In some cases he was successful, but to no great extent. At last he turned to the phonograph—an instrument which was practically unknown in this country, save as a clumsy toy. But a properly manipulated phonograph could repeat sounds, previously recorded, with mathematical precision. He had the good fortune to find that the sounds so carefully preserved in one zoological garden provoked interest, and were apparently quite intelligible to monkeys in other gardens in distant countries. His observations had hitherto been conducted with monkeys in captivity, but he was now on his way to the deep forests of Western Africa, once visited by Paul du Chaillu, in order to study the language and habits of the great apes. He was carrying with him an outfit of the most complete and unique character that had ever been brought into use for such purposes. He meant to live in a cage and to provide himself with an electrical apparatus. His cage was convertible, and weighed 320lb., and he could make four cages of it and bring home a gorilla in one of them.

AT the last prize contest instituted by the City of Paris for the best electric meter the prize of 5000 francs was awarded to Prof. Elihu Thomson. Desiring that this sum should serve for the development of the theoretical knowledge of electricity, Prof. Thomson requested M. Ernst Thurnauer, General Manager for Europe of the Thomson-Houston International Electric Company, to offer a prize for the best work on a theoretica question in electricity, and to organize a committee who should propose the subjects, examine the productions, and decide the prize. The following gentlemen have consented to act as members of the Committee:—J. Carpentier, President of the Société Internationale des Electriciens; Hippolyte Fontaine; E. Hospitalier, Professor in the School of Physics and Chemistry of the City of Paris; E. Mascart, Member of the Institute; A. Potier, Member of the Institute (Examiner); B. Abdank-Abakanowicz, Consulting Engineer (Secretary of the Committee). The Committee has decided that the prize should be given for an investigation on one of the following subjects:—(1) The heat developed by successive charges and discharges of condensers under different conditions of frequency, nature of dielectric, and quantity of charge. (2) It has been shown theoretically that when the two surfaces of a condenser are connected by a conducting body, the condenser becomes the source of alternating currents as soon as the resistance of the conducting body decreases below a certain limit. The formula that permits calculating the period of this oscillation has not yet been completely verified. This period of oscillation should be investigated experimentally under conditions such that the exact measure of resistance, capacity, and coefficients of self-induction may be possible, in order to arrive at a complete and precise verification of this formula. (3) When a condenser made with an imperfect insulating material has been charged and then left to itself, the charge is gradually dissipated. The time necessary for the charge to be reduced to a given fraction of its initial value depends only on the nature of the insulating material. It is proposed to investigate whether, as certain recent theories would seem to indicate, analogous phenomena do not present themselves in metallic conductors, and whether these can be shown experimentally. (4) It is proposed to arrange and systematize our present knowledge of the graphical solutions of electrical problems, and deduce from them some general methods as in graphical statics. The theses presented may be written in any one of the following languages:—English, French, German, Italian, Spanish, or Latin. They may be in manuscript or printed. Each thesis presented must be signed by a pseudonym and accompanied by a sealed envelope bearing the same pseudonym on the outside, and with the name and address of the author inside. The papers must be sent before September 15, 1893, to B. Abdank-Abakanowicz, Consulting Engineer, the Secretary of the Committee, at 7 Rue du Louvre, Paris, who will furnish any further information required.

THE additions to the Zoological Society's Gardens during the past week include a Black-handed Spider Monkey (*Ateles geoffroyi*) from Nicaragua, presented by Mr. F. Vyner; a Macaque Monkey (*Macacus cynomolgus* ♂) from India, presented by Mr. Gerald E. Bridge; a Black-shouldered Kite (*Elanus cæruleus*) captured at sea, presented by Mr. J. Watson; a Falcated Teal (*Querquedula falcata* ♂) from China, presented by Mr. A. C. Moule; an American Black Snake (*Coluber guttata*) from North America, deposited; two Mule Deer (*Cariacus macrotis* ♀ ♀) born in the Gardens.

OUR ASTRONOMICAL COLUMN.

THE STAFF AT THE LICK OBSERVATORY.—We are sorry to notice the very considerable changes that are now taking place in the staff at the Lick Observatory. It seems only quite recently that Prof. Keeler tendered his resignation to take over the directorship of the Allegheny Observatory, but now we hear that Mr. Burnham has resigned, and that Prof. Henry Crew has done the same, the former having accepted a position of clerk in one of the courts of Chicago, and the latter having been elected to a Professorship of Physics in the North-Western University at Evanstown, Ill. With the loss of these men the observatory will be crippled for some time; for, although very good men will be found to take their places, a thorough acquaintance with the instruments can be obtained only by constant and frequent practice. Of the remainder of the staff Mr. Barnard and Mr. Schaeberle will be the only representatives of the older members. What the cause of these changes is we do not know, but there seem to be signs of a little friction somewhere, for what is the probability that three men should sever their connection with such an observatory in the space of a year—assuming, of course, normal conditions?

THE OBSERVATIONS OF KLINKERFUES REDUCED.—The second part of the *Astronomische Mittheilungen of the Royal Observatory* in Göttingen contains a complete reduction of Klinkerfues' observations which he made in the years 1858 to 1863. The work has been undertaken by the Director of the Göttingen Observatory, Prof. Wilhelm Schur, and has been printed at the expense of the König. Gesellschaft der Wissenschaften zu Göttingen. In the introduction Prof. Schur gives a complete account of the instruments used and the methods by which the observations were made. The zone included in this work is that which lies between + 15° and − 15° declination. The interest that is attached especially to these observations is caused by the fact that Klinkerfues did not wish to adopt the usual method for determining the declinations directly from the readings of the vertical circles, but he used that generally known as Gauss' method, in which a mirror and scale played an important part. The epoch to which all the places are referred is that of 1860, and a table is also added by which the yearly precession in right ascension and declination can be easily determined.

PHOTOGRAPHS OF SOLAR PHENOMENA.—To the August number of *Astronomy and Astro-Physics* are contributed some striking pictures that represent some of the latest advances made by the application of the photographic plate to the telescope. These photographs were taken by Prof. G. E. Hale, of the Kenwood Astro-Physical Observatory, with the new spectroheliograph, a description of which instrument will be found in the May number of the same Journal. The first photograph displays the spots and faculæ on the solar surface on May 21 last: a single glance at it will show us that we shall have to change very considerably our present ideas as to their extent, for instead of equalling the spots in area they exceed them so much as to place them relatively in entire insignificance. Another point that is at first noticed from the same photograph is the paucity of the faculæ at the limb with respect to the more central part of the disc, but this is, as we are told, only a fault in the process of reproduction, for in the original negatives the faculæ "are equally well shown on all parts of the solar surface." Another photograph of interest is that of the chromosphere and prominences taken on the same day; this was obtained by cutting off the light issuing from the solar disc by means of a metallic diaphragm; it resembles very strikingly a short-exposed photograph of the eclipsed sun, as the prominences on it as distinctly visible, while the presence of streamers and rifts is lacking. Since these photographs were taken, Prof. Hale has been able, by making two exposures on the same plate, to produce pictures each of which displays all the solar phenomena. For the first exposure he employed the metallic diaphragm, allowing the slits which move across it to travel with the velocity required for the prominences; for the second exposure the diaphragm was removed, and the rate of movement of the slits was this time very much increased.

A METEORITE.—In the *American Journal of Science* for August, Mr. H. L. Preston gives an account of the finding of a meteorite in Kenton County, eight miles south of Independence. In the year 1889 during the cleaning out of a spring, something very hard was struck which from the sound was thought to be metal. It was entangled among the roots of an ash tree three or four feet down in the ground, and was not removed from the spot until August 1890, when it was placed in a shed, and more recently bought for the Ward collection of meteorites. The measurements along its greatest diameters were 21 × 14 × 8 inches, and it weighed 359½ pounds. Its surface was covered with numerous but mostly shallow pittings, but was entirely free from crust. An analysis showed that it contained iron to the amount of 91·59 per cent., nickel 7·65, cobalt 0·84, carbon 0·12, with traces of copper and sulphur.

MOUNTING OF OBJECTIVES.—A novel but very useful way of mounting objectives is that adopted by Prof. Hale, who has added another object glass to his equatorial. What he has done has been to employ a twin cell in which the glasses have been placed; the whole is then hung on an axis fixed rigidly to the side of the telescope tube so that by a simple rotation each glass, whether for photographic or for visual purposes, can be brought to the centre of the front of the tube. In order to make use of that objective which is not temporarily required for the main instrument, a tail-piece near the eye-end is also mounted, thus completing another telescope, only without a tube. One great disadvantage of this arrangement would be the difficulty of centring the lenses after each change, but this is not so as we are informed, no difficulty at all being experienced. In *Astronomy and Astro-Physics* for August, there is shown a picture of Mars emerging from occultation on July 11, taken without the tube. In the original photograph, which is about $\frac{1}{32}$ inch in diameter, the polar caps on the planet are clearly shown together with some of the other markings on the surface.

JUPITER.—During the next two months the planet Jupiter will be in a very good position for observation. This year he is as much as 5° to 8° north of the equator, being situated now in the constellation of Pisces, just north of the two stars μ and ν. The next opposition occurs on the 12th October.

NOVA AURIGÆ.—In a communication to the *Daily Graphic*, the Rev. A. Freeman gives the results of some observations of the revived new star in Auriga, made by him on Sunday, August 28. Adopting Mr. Stone's values for the magnitudes of the neighbouring stars, the nova would appear to have then been a trifle brighter than mag. 10·3, but decidedly fainter than 9·7. By comparison with the zone star +30° 924. the nova was rated at mag. 10·1. As Mr. Espin estimated it to be 9·2 on August 21, it is probable that the star is again waning.

From the Astrophysical Laboratory at South Kensington we have received the following:—There was no opportunity of observing the nova here until 1.30 a.m. on Thursday, September 1, and it was then too dim to be readily seen with the 10-inch refractor. A photograph of the region was taken with the 3½-inch portrait lens, the exposure being thirty minutes, but this failed to show the nova, although clearly showing stars of the 10th magnitude.

COMET SWIFT, MARCH 6, 1892.—The following is a continuation of the ephemeris for Comet Swift, which we take from *The Edinburgh Circular*, No. 29:—

1892.	R.A. h. m. s.	Decl. ° ′	log. Δ.	log. r.	Br.
Sept. 8	0 32 27	+51 56·5			
9	31 8	51 48·8			
10	29 49	51 40·7	0·2751	0·4085	0·073
11	28 30	51 32·1			
12	27 10	51 23·2			
13	25 50	51 13·9			
14	24 30	51 4·1	0·2788	0·4164	0·069
15	23 11	50 54·0			

Brightness at time of discovery is the unit of Br.

The Edinburgh Circular, No. 30, announces the discovery of a comet by Mr. Brooks, at Geneva, U.S., at midnight on the 29th ult. The comet was then in R.A. 6h. 20min. and declination 31° 48′ north, its daily motion being +1min. 44sec. and 2′ south. The same comet has also been observed at Kiel on the 31st inst. at 12h. 32·2min.; its place then was found to be R.A. 6h. 5min. 59·1sec. North declination 31° 42′ 27″. Whether this comet is a new one or not cannot of course be said yet for certain, but it is neither Brooks' 1886 IV. nor Tempel 1867 II. if we can depend on the two search ephemerises we have at hand, for their declinations in both instances should be at this time over 30° south.

GEOGRAPHICAL NOTES.

MONTENEGRO, though one of the smallest, is certainly one of the least known countries in Europe. Dr. K. Hassert, who has already made important journeys in the less known parts of the Balkan peninsula, is this summer travelling through Montenegro, and describes the scenery as in many places of very great beauty. The frontier river Cijevna flows through a steep-sided gorge, the height of the precipices bordering which he estimates as over 3000 feet, while in its appearance it rivals the cañons of the Colorado. The traveller in this part of the country runs considerable risks from the predatory Albanian tribes.

THE *Times* publishes a telegram from Captain MacDonald of the Mombasa-Victoria-Nyanza Survey, announcing that the Survey had found a good route for a railway to Sio Bay on the Nyanza, and had returned to Kikuyu on August 8. The Survey work has been carried on rapidly, and, which is more important, without any fighting.

RAILWAYS in tropical Africa may ultimately derive more revenue from native passengers than might be anticipated. The railway from St. Paul de Loando is being pushed forward to Ambaca, and now nearly reaches Casengo, where there are flourishing coffee plantations under Portuguese management. Until this point is reached the revenue from goods cannot be large, but the natives having speedily got over their distrust of the innovation, now travel freely by rail in large numbers.

PROF. POUCHET has this summer succeeded in visiting Jan Mayen Island and Spitzbergen in the French gun-boat *La Manche*. Jan Mayen, on which a landing had not been made for ten years, was visited on July 27, and the vessel proceeded to Spitzbergen, where a fortnight was spent. The west coast was followed up to 78° N., and some excursions made on foot into the interior. Glacier phenomena were studied, and collections of native fauna and of fossils made. The sea was found to be entirely free from ice.

NEWS has recently been received in Copenhagen of the safety and success of the East Greenland Expedition, which left Denmark in June 1891 under Lieutenant Ryder. The expedition passed the winter on the Greenland coast in Scoresby's Land at a point in 70° 27′ N. Important scientific results have been obtained, but the expedition is not yet over, Lieutenant Ryder intending, after a short visit to Iceland, to make an attempt to trace out the hitherto unvisited coast-line between 70° N. and the Arctic circle.

THE first chart on which the American continent appears is being reproduced in facsimile for the approaching Columbus Exhibition in Madrid. The following details are given in a Reuter telegram from Madrid. The work, which is now approaching completion, is being done by Señor Canovas Vallejo, a nephew of the Spanish Premier, and by Prof. Traynor. The original chart, which was traced in the year 1500 by the famous navigator and cartographer Juan de la Cosa, who acted as pilot to Columbus in more than one of his voyages across the Atlantic, has been since carefully preserved in the Naval Museum in Madrid. The chart presents some most interesting features, displaying, as it does, the extent of the knowledge of the best-informed geographers of the day. On it are depicted the West Indies and a small portion of South America—namely, the north-eastern section lying between the River Amazon and Panama. To this land the general name of Tierra Firme is given, to mark the contrast between the continent and the Antilles. Here and there are traces of modern names, such as Venezuela, Maracaibo, and Brazil. The chart even comprises some particulars of the discoveries made in Northern America by Sebastian Cabot in 1497, and such titles as these:—"Sea discovered by the English," "English Cape," "Lizard," and "St. George." La Cosa has also clearly depicted Cuba as an island, whereas Columbus died in the belief that it was a continent, and it was not until eight years later that the correctness of La Cosa's chart was in this respect finally established.

AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

ROCHESTER MEETING.

THE forty-first annual meeting of the American Association for the Advancement of Science was held at Rochester, New York, August 17–23, Prof. Joseph Le Conte, of California, the well-known geologist, presiding.

Rochester is one of the most beautiful of American cities, being laid out quite on the *rus in urbe* principle, so that each residence is generally surrounded by grounds, instead of being built in a solid block. It is pre-eminently a city of freeholders, as appears by the fact that a recent census showed more landowners than voters in the city. It is moreover situated in the beautiful and picturesque region of western New York, within a very short distance from numerous glacial lakes, as well as the

Falls of Niagara. The fertile valley of the Genesee was long ago renowned for its wheat as it now is for its fruit and flowers, and Rochester, formerly called the flour city, is now known as the city of flowers. The river flows through the city, falling in pretty cascades to a wild glen, and furnishing the water power which is utilized in flouring mills and other manufactures. Lake Ontario is a few miles distant, but yet it is so far away, and the navigation of the Genesee is so restricted, that Rochester is considered an inland city, and it is the largest inland city in the United States, having a population of 144,000.

The meeting of the Association coincided in time with the railroad strikes at Buffalo, some seventy miles distant, where several regiments of militia were stationed at that time to protect the railroads from mob violence. The sense of insecurity doubtless deterred a few members from attending, though the attendance was above the average.

For the last few years, specialists have shown a growing tendency to organize special societies outside of, though affiliated to, the general Association. This year the larger meeting was preceded by meetings of the American Microscopical Society, the Geological Society of America, the Society for the Promotion of Agricultural Science, the Association of Economic Entomologists, and this year was organized the American Association of State Weather Services. The latter is composed of weather observers from the several States of the Union. Every State now has a weather-observing station, and an observer co-operating with the general government.

The first day of the meeting was taken up with opening general exercises, organizing the sections, and addresses by the retiring president, Prof. Albert B. Prescott, of Ann Arbor, and the presidents of the several sections, namely, mathematics and astronomy, J. R. Eastman; physics, B. F. Thomas; chemistry, Alfred Springer; mechanical science and engineering, J. B. Johnson; geology and geography, H. S. Williams; biology, S. H. Gage; anthropology, W. H. Holmes; economic science and statistics, Lester F. Ward.

The remaining days of the meeting were given to reading of papers in the various sections, after a brief business meeting in general session. The general business included a division of the biological section into Section F, zoology, and Section G, botany, the former Section G, microscopy, having been abolished years ago. The biological section has long been overcrowded.

The preservation of forests has been and is one of the most important economic matters of our age. Reckless and wasteful methods have prevailed to such an extent that many fine forests have been ruined, and others are rapidly going to ruin. The large areas still owned by government are subject to the double peril of robbery and fire. Mr. Fernow, chief of the Bureau of Forestry, in a paper before the economic section, stated that the annual loss to the government by thieves is 10,000,000 to 15,000,000 dols., while that by fire is probably twice as much more. To protect the twenty thousand square miles of government forest land, a paltry force of twenty to twenty-four watchmen is employed, and even these are not clothed with sufficient authority. They are barely able to reclaim some 100,000 dols. worth of timber annually from depredators, which only suffices to repay the expense of maintaining the service. Proper protection would require an annual outlay of 2,000,000 dols. to 3,000,000 dols., and would preserve 20,000,000 to 50,000,000 dollars' worth of property in each year. The section recommended a resolution favouring suitable legislation, such as is embodied in the bill introduced by Senator Paddock, and the resolution was unanimously adopted in general session.

Much interest was manifested in the approaching World's Columbian Exposition at Chicago. Prof. F. W. Putnam, permanent secretary of the Association, is also chief of the department of ethnology, &c., at the Exposition. In a paper before the anthropological section he detailed plans adopted for taking anthropmetrical measurements of native American tribes, also of children in public schools, both white and others, as well as children in the Indian schools. An exhibit of special interest will be a collection of representatives of all the native American tribes, including a family from each tribe, engaged in native industries. This will require the gathering of at least five hundred aborigines, and probably more than that number, and it will be the last opportunity when such an exhibit can be made, since the extension of railroads and other appliances of civilization is rapidly subverting aboriginal methods and conditions; the tribes are becoming disintegrated and amalgamated, and machine-made articles are supplanting those by hand.

Committees were appointed from each section to co-operate with other organizations having similar aims, in holding joint meetings during the Exposition. By resolution in general session the Secretaries of the several sections were appointed a committee to co-operate with the World's Congress Auxiliary in securing space for each section for the entire time of the Exposition in which to register as headquarters for that section, and similar organizations, both foreign and domestic.

Thursday evening was occupied with a reception by the Women's Reception Committee of the Local Committee at the Powers Art Gallery. This is by some considered to be the finest art collection in America, including pictures by Diaz, Corot, Millet, Verboeckhoven, Gérome, Munkacsy, Doré, Bonheur, Vibert, Bougereau, Zimmerman, Cooman, Leloir, Hagborg, Schreyer, Henner, Le Rolles, Knaus, Jackobides, Defregger, Daubigney, Rousseau, and other foreign artists, besides works of the best American artists, and copies of Rubens, Titiens, Raphael, Correggio, and others.

Besides the annual address of the retiring President, Prof. Prescott, only one other address was made in general session. This was by Dr. Joseph Jastrow on Friday evening on "Hypnotism and its Antecedents." In the first part of his lecture he gave a historical sketch of the development of hypnotism, and described various procedures in which it is involved. The careers of Messmer and other early hypnotists were sketched, up to the time when it obtained scientific recognition about fifteen years ago through the efforts of Charcot and Richet. The second part of the lecture described the chief phenomena of modern hypnotism as revealed and recognized during the last score of years. The lecturer illustrated the illusions of sense in various ways, and described in detail the methods of inducing the state. In some instances, it was stated, the subject may not lose control, but simply finds it impossible to resist the demands of the operator. For instance, upon being told that he cannot open his eyes, he finds it impossible to do so, though perfectly conscious; a cane placed in his hands he is unable to drop, and fingers set in motion he is powerless to stop. Many interesting phenomena were cited. One of the most curious of these is what is termed the post-hypno suggestion. While the subject is asleep it is suggested that he shall perform some act at a certain time after awakening. These acts are performed by the patient, sometimes even when the time set to elapse has been a year. But perhaps the most surprising of all the phenomena cited was the control of the patient over involuntary powers. Upon being told that a postage stamp placed on the arm is a plaster which will raise a blister, the effect is actually accomplished. Sometimes the mere tracing of a line upon the skin has produced the same effect. In some cases rigidity of the muscles is induced, so that the arm may be kept extended or the body may be rigidly supported, with the head on one chair and the feet on another, for a long time. Important legal questions may be raised as to the responsibility of hypnotized patients. Crimes may be committed at the instigation of the operator. It has long been known that petty crimes could be so caused. It is found also that the gravest crimes are equally controlled, as shown by repeated instances where the patient was given a dagger and told to stab a person lying on a certain cot in the hospital, which the patient did, though the person stabbed was only a straw figure, but so covered as not to be recognized as such. The control over the nervous system renders hypnotism a valuable remedial agent in paralysis, aphasia, tetanus, and many other diseases controlled by or specially related to the nervous system.

Another lecture, which was practically tantamount to a public address before the Association, was that of G. K. Gilbert, President of the Geological Society of America, before the Rochester Academy of Sciences, on "Coon Butte and Theories of its Origin." This extinct crater, located in Eastern Arizona, is unique in showing no signs of lava or scoriæ, and also in the fact that meteoric iron is found abundantly near it, numerous specimens, one of them over 600 pounds in weight, having been picked up here. This suggested to Prof. Gilbert the hypothesis that the crater may have been caused by the impact of a larger meteor, sufficient to make such a hole three-quarters of a mile in diameter, just as a cannon ball fired into a target would do, especially as the general appearance of this crater is remarkably similar to that of some results caused by projectiles. To test the correctness of this theory, he caused a careful magnetic and geodetic survey to be made to determine whether any large mass of iron was buried beneath the crater, and also whether the rim exceeded the crater in bulk sufficiently to indicate a mass of matter in the rim larger than would be caused by the displacement of the material removed from the crater. Both these surveys, however, gave negative results. The magnetic survey indicated that if any considerable mass of iron exists there it is buried at least fifty miles deep, and a comparison of the quantity of matter in the rim shows no more than would fill up the space of the crater. He was compelled, therefore, to abandon the meteoric theory, notwithstanding that the chances of the fortuitous concurrence of such a crater accompanied by such a meteoric downfall is only one in five thousand. The origin of the butte must therefore be an explosion of steam.

The president elect of the Association, Prof. William Harkness, of Washington, was born at Ecclefechan, Scotland, in 1837, where his father, Rev. James Harkness, resided till 1839, when the family removed to America. The father was for a while pastor of a church at Rochester, where the son was educated, after having spent part of his college life at Lafayette College, in Pennsylvania. He graduated at the University of Rochester in 1858, and received from the same university the degree of doctor of laws in 1874. It was, therefore, peculiarly appropriate that he should be elected to the presidency at the Rochester meeting.

Prof. Harkness studied medicine, and practised as an army surgeon in 1864; but, with the exception of a short time in the army, he has been employed by the Government as an astronomer for about thirty years. During the total eclipse of 1869, he discovered the 1474 line of the spectrum of solar protuberances. He became prominent in observations of the transits of Venus.

It is difficult to select the most important and valuable papers from the whole number of 182 read before the several sections, but a few abstracts will be subjoined which appear to merit notice.

George E. Hale, of Chicago, read a paper before the astronomical section on "The Spectroheliograph of the Kenwood Astro-physical Observatory, Chicago, and results obtained in the study of the Sun." He described the ingenious apparatus which he had invented and perfected for photographing the faculæ and protuberances of the sun. This apparatus gives by far the most perfect pictures ever taken, and is the first which has successfully photographed the bright spots, showing faculæ which the eye cannot detect. Means were devised for taking on the same plate at one exposure both the faculæ and the protuberances, and Prof. Hale exhibited the first complete picture of the sun ever taken. Comparison with the best plates made at the Lick Observatory showed the great superiority of the work at Chicago. An observation of unusual interest was made on July 15, 1892. A photograph of the sun showed a large spot. A few minutes later another photograph was taken, which, when developed, showed that the bright band had appeared since the last exposure. Twenty-seven minutes thereafter another photograph showed that almost the entire spot was covered with brilliant faculæ, which by the end of an hour had entirely disappeared, leaving the spot as at the first exposure. This indicates an eruption proceeding with indescribable and inconceivable velocity. This disturbance seems to be connected with magnetic disturbances and the brilliant aurora noted the next day. The section, with much enthusiasm, passed a vote of thanks to Prof. Hale for his researches.

Edwin B. Frost read a paper on "Thermal Absorption in the Solar Atmosphere." Among the interesting phenomena observed were some cases where the umbra of sun spots radiated more heat than the neighbouring photosphere, indicating either that the dark spot is at a higher elevation than the surrounding photosphere, and consequently loses less heat by absorption of the sun's atmosphere, or that it is attended by an invisible facula.

Prof. R. S. Woodward described the iced-bar base apparatus lately devised by him for the Coast and Geodetic Survey. This is a line measure, micrometer microscope apparatus. The measuring bar is of steel, five metres long, and its temperature is kept constant by a packing of melting ice. The use of thermometers is thus avoided entirely. From results submitted by the author it appears that the total probable error of one measure with this apparatus of a distance a kilometre or more in length will not exceed one part in four to five millions.

One of the most important uses to which Prof. Woodward has applied the iced-bar apparatus is that of showing that long steel tapes, when properly handled, will give from one measure the length of a line, a kilometre, or more long with a probable error not exceeding one part in a half-million. Considering that this can be done at the rate of two kilometres per hour with a 100-metre tape, it would seem that such tapes must soon take high rank amongst apparatus for measuring bases.

Prof. W. A. Rogers read two papers before Section D, the first of which was a description of a standard yard and metre upon polished steel. The standard, which was exhibited, had upon one edge a metre subdivided by 20 millimetres and 40 inches subdivided to tenths of inches. Both are standard or 62° Fahr. It appears from an investigation of these standards that 772 of the separate millimetres have errors not exceeding one mikron, and that of the 400 tenth-of-inch spaces 280 have errors not exceeding one-twenty-five-thousandth of an inch.

Prof. Rogers read a second paper on an investigation of a 21-foot screw. This screw was made by the Pratt and Whitney Company for R. Hoe and Co., of New York. It appeared from this investigation that the pitch of this screw was very regular in its character, but that the linear error amounted to nearly one-hundredth of an inch in 21 feet. A part of this is undoubtedly due to flexure, but a part is due to changes of pitch in the screw itself.

In the section of anthropology Permanent Secretary F. W. Putnam gave an interesting talk on "Copper Implements and Ornaments in the Ohio Mounds." He emphatically denied the statements that these copper instruments were fashioned by white men and given to the Indians in trade. "It must be," said he, "that these implements were made by the native Americans. In all cases where implements and ornaments are found in these mounds there are found also on the altars nuggets of copper. So it is with the silver implements and those made of meteoric iron. Now, is it likely that the trader would furnish the Indian with nuggets of the natural material? There is conclusive proof that the original settlers of the Ohio Valley worked the metal into these implements and ornaments. Again, many of these mounds have trees growing on them that are between 400 and 500 years old. This carries them back beyond the time of trading." Prof. Putnam explained that holes could be cut in the sheet copper which had been hammered out by the Indian by simply placing the sheet of copper on the trunk of a tree and pounding into it one end of an oak limb squared. He was unable to describe the probable mode adopted by the Indians in cutting edges shaped like the teeth of a saw, but thought it was done by the use of an instrument made of meteoric iron.

In the section of biology, C. V. Riley read a paper on "Fertilization of the Fig and Caprification." In the production of the best Smyrna figs certain minute insects perform an essential function in fructifying the fig. The process is called "caprification," and has been performed by the aid of fig-growers ever since the time of Aristotle. The cultivator is accustomed at a certain season to place the fruit of the "caprifig," which contains these insects, on the fig tree which contains the edible fig. The caprifig does indeed produce a fig, but it is small and insipid. The tree which produces the edible fig does not yield fruit of fine flavour unless it is thus fertilized by the aid of these insects, the scientific name of which is Blastophaga psenes. The absence of these explains the insipidity of figs raised in California. There are, indeed, a dozen species of Blastophagæ found in America, but it is improbable that any one of them is adapted to the fertilization of the Smyrna fig, which growers there are trying to cultivate. The caprifig, however, is already well established, and the desideratum seems to be to introduce the insects. This, Prof. Riley thinks, can be done by gathering the fruit containing them in Smyrna and rapidly transporting it to California, which, he urges, should be undertaken by the Government. An attempt was made last summer by J. Shinn, of Niles, Alameda County, California. The fruit containing insects was gathered at Smyrna in the last days of June and received at Niles on July 23, within twenty-five days, but it is not known whether the experiment was successful.

In the section of physics, several valuable papers were contributed by G. W. Hough, A. E. Dolben, W. L. Stevens, E. L. Nichols, B. W. Snow, and others. One of the most interesting papers giving results of original research was by Edwin S. Ferry on "Persistence of Vision."

Prof. Frank P. Whitman, in a brief paper on the "Magnetic Disturbances caused by Electric Railways," gave the following results of recent observations:—"No magnetic instruments dependent on the earth's field can be used for reasonably accurate work at less than 1500 feet from an electric railway, and the distance must be made greater still if the building in which the instrument is placed is fitted with a system of iron pipes. Minor galvanometers must use iron shields and artificial fields, while earth indicators and other similar methods of finding the constant of a ballistic galvanometer must be abandoned. Experiments are under way for providing the thinnest shield of soft iron which will serve as complete protection to magnetic instruments under such conditions as just mentioned."

The preliminary meetings of affiliated societies drew off much material which would otherwise have been presented to the chemical and zoological sections.

Prof. Robert T. Hill read to the geological section a paper on "The Volcanic Craters of the United States," in which he said:—"At the present moment, when many of the great volcanoes of the world are in activity, Vesuvius and Etna in Europe, others in the Australian region, and Colima in Mexico, I thought it a good idea to review the many beautiful volcanic craters found in our own land. The great cinder cones of New Mexico, Arizona, California, and Oregon are among the most interesting. The most eastern crater in the United States is Mount Capulin, a vast mountain in New Mexico. This is composed of volcanic cinder, which looks very much like that which comes from a locomotive. It rises 2750 feet above the plain on which it stands. It is twelve miles in circumference at its base. Were it situated in the eastern part of the United States it would be considered one of the greatest objects of natural interest, but in the West, where the phenomena are so abundant, it is hardly noticed and it has not found a place on the maps. In Arizona and New Mexico over 300 old volcanic necks or 'pipes' are found, and there are 20,000 square miles of lava which has flowed from them. The recent earthquakes in California were shown to have been produced by the terrific volcanic disturbances in Western Mexico."

Prof. Hill thinks it probable that the extinct volcanoes in the United States may again become active. The volcanic region has only been known about fifty years, and experts say that appearances indicate eruptions within two hundred years past.

The next meeting of the Association will be held at Madison, Wisconsin, on the third Thursday of August, 1893, unless the date shall be changed by the council.

Cordial invitations from the city government of San Francisco, the California Academy of Science, the University of California, and the new and munificently-endowed Leland Stanford, Jun., University, indicate that a meeting at San Francisco will be arranged for 1895.

THE INTERNATIONAL CONGRESS OF ORIENTALISTS.

THE meetings of the International Congress of Orientalists are being held this week in London, and the proceedings, which are of great interest, have been attracting a good deal of popular attention. The Congress is being attended not only by a large number of British scholars, but by many representatives of other countries, among whom are the following:—Austria-Hungary: Prof. G. Bühler, the Rev. Joseph Dahlmann, Dr. I. Goldziher, Dr. J. Karabacek, Prof. L. Reinisch; Belgium: Dr. Abbeloos; Egypt: Dr. Vollers; France: Prof. J. Darmesteter; Germany: Prof. K. Abel, Prof. R. E. Brünnow, Prof. Geiger, Prof. Hommel, Prof. Hübschmann, Dr. G. Huth, Prof. Kautzsch, Prof. Kielhorn, Prof. Leumann; Holland: Prof. J. P. N. Land; Italy: Prof. Ascoli, Dr. Carlo Formichi, Count Angelo de Gubernatis, Dr. Pavolini; Sweden and Norway: Dr. Karl Piehl; United States of America: Prof. Charles Lanman, Mr. W. H. Ward.

At the opening meeting on Monday, Prof. Max Müller delivered his presidential address. After some preliminary observations, in the course of which he expressed the obligations of the Congress to the Duke of York for having consented to act as honorary president, Prof. Müller spoke of the splendid service which has been rendered by Oriental scholarship in proving that in prehistoric times language formed a bond of union between the ancestors of many of the Eastern and Western nations, and that in historic times also, language, which seemed to separate the great nations of antiquity, never separated the most important among them so completely as to make all intellectual commerce and exchange between them impossible. These two discoveries seemed to him to form the highest glory of Oriental scholarship during the present century. It was often supposed that students of Oriental languages and of the science of language dealt with words only. Even now, when scholars spoke of languages and families of languages, they often forgot that languages meant speakers of languages, and that families of speech presupposed real families, or classes, or powerful confederacies which have struggled for their existence and held their ground against all enemies. "Languages," said Prof. Müller, "as we read in the book of Daniel, are the same as nations that dwell on all the earth. If therefore Greeks and Romans, Celts, Germans, Slavs, Persians, and Indians, speaking different languages, and each forming a separate nationality, constitute, as long as we know them, a real historical fact, there is another fact equally real and historical, though we may refer it to a prehistoric period, namely, that there was a time when the ancestors of all these nations and languages formed one compact body, speaking one and the same language, a language so real, so truly historical, that without it there would never have been a real Greek, a real Latin language, never a Greek Republic, never a Roman Empire; there would have been no Sanskrit, no Vedas, no Avesta, no Plato, no Greek New Testament. We know with the same certainty that other nations and languages also, which in historical times stand before us so isolated as Phenician, Hebrew, Babylonian, and Arabic, presuppose a prehistoric, that is, an antecedent powerful Semitic confederacy, held together by the bonds of a common language, possibly by the same laws and by a belief in the same gods. Unless the ancestors of these nations and languages had once lived and worked together, there would have been no common arsenal from which the leading nations of Semitic history could have taken their armour and their swords, the armour and swords which they wielded in their intellectual struggles, and many of which we are still wielding ourselves in our wars of liberation from error, and our conquests of truth."

With regard to the question as to the exact part of the world where these consolidations took place, no definite or positive statement could be made. Nothing, however, had shaken his belief—he did not call it more—that the oldest home of the Âryas was in the East. All theories in favour of other localities, of which so much had been said lately, whether in favour of Scandinavia, Russia, or Germany, rested on evidence far more precarious than that which was collected by the founders of comparative philology. There was also a difference of opinion as to the original home of the Semites, but all Semitic scholars agreed that it was "somewhere in Asia." With regard to time the difficulties were still greater; but Prof. Müller expressed the opinion that if we must follow the example of geology and fix chronological limits for the growth of the Proto-Aryan language, previous to the consolidation of the six national languages, 10,000 B.C. would by no means be too distant as the probable limit of what he would call our historical knowledge of the existence of Aryan speakers somewhere in Asia. There must also have been a long period previous to the formation of the great Semitic languages, because thus only can the fact be accounted for that on many points so modern a language as Arabic is more primitive than Hebrew, while in other grammatical formations Hebrew is more primitive than Arabic. Whether it was possible that these two linguistic consolidations, the Aryan and Semitic, came originally from a common source was a question which scholars did not like to ask, because they knew it did not admit of a scholarlike answer. Another question also which carried us back still further into unknown antiquity, whether it was possible to account for the origin of languages or rather of human speech in general, was one which scholars eschewed, because it was one to be handled by philosophers rather than by students of language. The deeper we delved the farther the solution of this problem seemed to recede from our grasp; and we might here too learn the old lesson that our mind was not made to grasp beginnings. And yet, though accepting this limitation of their labours as the common fate of all human knowledge, Oriental scholars had not altogether laboured in vain. No history of the world could in future be written without its introductory chapter on the great consolidations of the ancient Aryan and Semitic speakers. It might be said that this great discovery of a whole act in the drama of the world, the very existence of which was unknown to our forefathers, was due to the study of the Science of Language rather than to Oriental scholarship. But where would the Science of Language have been without the students of Sanskrit and Zend, of Hebrew and Arabic? "At a

Congress of Orientalists we have a right to claim what is due to them, and I doubt whether anybody here present would deny that it is due in the first place to Oriental scholars, such as Sir W. Jones, Colebrooke, Schlegel, Bopp, Burnouf, Grimm, and Kuhn, if we now have a whole period added to the history of the world, if we now can prove that long before we know anything of Homeric Greece, of Vedic India, of Persia, Greece, Italy, and all the rest of Europe, there was a real historical community formed by the speakers of Aryan tongues, that they were closely held together by the bonds of a common speech and common thoughts. It is equally due to the industry and genius of Oriental scholars such as de Sacy, Gesenius, Ewald, and my friend the late Prof. Wright, if it can no longer be doubted that the ancestors of the speakers of Babylonian and Assyrian, Syriac, Hebrew, Phenician, and Arabic formed once one consolidated brotherhood of Semitic speech, and that, however different they are when they appear for the first time in their national individuality on the stage of history, they could once understand their common words and common thoughts, like members of one and the same family. Surely this is an achievement in which Oriental scholarship has a right to take pride, when it is challenged to produce its title to the gratitude of the world at large."

Turning to another field, Prof. Müller showed that Oriental scholars had inspired the oldest period in the history of the world with a new life. Instead of learning by heart the unmeaning names of kings and the dates of their battles, whether in Egypt or Babylon, in Syria or Palestine, we had been enabled, chiefly through the marvellous discoveries of Oriental scholars, to watch their most secret thoughts, to comprehend their motives, to listen to their prayers, to read even their private and confidential letters. The ancient history of the world might be said to have assumed, under the hands of Oriental scholars, the character of a magnificent dramatic trilogy. The first drama told us of the fates of the Aryan and Semitic races, as compact confederacies before their separation into various languages and historical nationalities. The second drama was formed by the wars and conquests of the great Eastern Empires in Egypt, Babylon, and Syria, but it showed us that besides these wars and conquests, there was a constant progress of Eastern culture towards the West, towards the shores and islands of the Mediterranean, and lastly towards Greece. The third drama represented the triumphant progress of Alexander, the Greek far more than the Macedonian, from Europe through Persia, Palestine, Phenicia, Egypt, Babylon, Hyrcania, and Bactria to India, in fact through all the great empires of the ancient East. Here we saw the first attempt at re-establishing the union between East and the West.

Prof. Müller concluded his address with an eloquent and impressive plea for the encouragement of Oriental studies in England. "When," he said, "I accepted the honourable post of president of this congress, it was chiefly because I hoped that this congress would help to kindle more enthusiasm for Oriental scholarship in England. But that enthusiasm must not be allowed to pass away with our meeting. It should assume a solid and lasting form in the shape of a permanent and powerful association for the advancement of Oriental learning, having its proper home in the Imperial Institute. If the members of this congress and their friends will help to carry out this plan, then our congress might hereafter mark an important epoch in the history of this the greatest Eastern Empire, and I should feel that, in spite of all my shortcomings, I had proved not quite unworthy of the confidence which my friends and fellow-labourers have reposed in me."

A vote of thanks to Prof. Müller for his interesting address was moved by Prof. von Bühler, seconded by Count de Gubernatis, and carried with enthusiasm.

On Tuesday the work of the sections was proceeded with. Special interest was given to the proceedings on Wednesday by the reading of an address written by Mr. Gladstone, for the section dealing with Archaic Greece and the East.

THE ERUPTION AT SANGIR.

ON Friday last the *Times* printed some interesting extracts from a letter (dated Labuan, July 11, 1892) by Mr. George Ormsby, a magistrate in the British North Borneo Company's Service, containing an account of the recent eruption in Sangir, and of a visit paid to the spot immediately afterwards. Mr. Ormsby left Sandakan on June 4 in the s.s. *Normanby*, and arrived at Menado on the morning of the 7th. After a visit to Govontalo the vessel returned to Menado on the 10th, and here Mr. Ormsby heard that there had been an eruption on some of the islands to the north, and that the s.s. *Hecuba*, which had arrived at Menado just after the *Normanby* had started for Govontalo, had been chartered by the Dutch Government, and had gone out to find the scene of the eruption and to render assistance. On the 12th the *Hecuba* was sighted coming into Menado, and Mr. Ormsby and the skipper of the *Normanby* went on board as soon as she dropped anchor. "The captain," says Mr. Ormsby, "told us that he first went to an island called Siow, as the volcano there was known to be active. He found the island covered with ashes, but was told that the eruption had taken place at Sangir, an island about 30 miles further north. He went on there, and found it buried in ashes; they were digging the houses out at Tarona, the port. The cocoanut trees were all destroyed, and the loss of life was unknown. The volcano was slightly in eruption when he arrived. He went along the coast, stopping at the villages, and sending rice ashore, as the people were without food. He said some of the people were frightfully burned and maimed."

When the Dutch official who was on board the *Hecuba* reported the state of affairs to the Resident, the *Normanby* was chartered to take rice to the island and land it at Tarona. She left Menado at midnight, and arrived at Tarona next afternoon. "As we steamed up the coast of Sangir we could see the cocoanuts, with all the leaves broken and hanging downwards and covered with ashes, although the southern end of the island is sheltered from the volcano by hills. The harbour of Tarona is a narrow inlet, about half-way up the western side of the island, with steep hills on each side. The village is on the north side of the harbour, and is sheltered from the volcano by the hills behind it; behind the hills a large plain stretches to the foot of the volcano."

The eruption took place on the 7th at 7 p.m., and there was a slight eruption on the 9th, followed by heavy rain. The only damage done in Tarona was by the weight of ashes; many of the lightly-built native houses were crushed. "The afternoon we arrived," Mr. Ormsby says, "I went ashore, and followed the road from Tarona along the harbour. On rounding the end of the hills the road turned and ran along the northern slope of the hill; down below the road there was a deep ravine, with a small stream at the bottom, which was warm and smelt strongly of sulphur. The ravine was 40 ft. or 50 ft. deep, and had evidently been partly cut out by a stream of mud, which had rushed down it from the foot of the mountain and torn away the road in places. Looking across the ravine towards the crater the whole plain was burnt up, and near the foot of the mountain there was a jet of steam and thick black smoke. On the slope of the crater there was no sign of lava or mud. The three mud rivers I saw started from the foot of the mountain. I followed the road for some distance. About two miles from the sea it crossed a small triangular plain, and then zigzagged up the central range of hills. Where it crossed the plain it was entirely washed away by mud and ashes, which had been hardened by the rain after the eruption. The bridge across the stream was also destroyed, only the butts of the piles remaining. I got up to the top of the hills and a bit down the other side. I had a fine view of the volcano from the top; it was smoking, but there were no fireworks while we were on the island. I noticed a column of steam rising from the plain, close to the foot of the volcano, and determined to try and reach it next morning."

The column of steam was visited next day by Mr. Ormsby and the chief engineer, but they reached it with difficulty. On the way they had to jump a "stream which was steaming, and must have been very hot." He says:—"We went up to where the steam was blowing up through the mud. The mud was quite firm, but so hot that we had to shift from one foot to the other. The steam was puffing up through a lot of holes, but not very strongly where we were. I poked up a lot of stones out of one of the holes with my stick; they were so hot you could not hold them. I let two of them cool a bit, and then rolled them up in my handkerchief and put them in my pocket. One of them was covered with sulphur crystals, but, unfortunately, I lost it as we were returning. The whole place smelt strongly of sulphur, and we soon decided we had had enough of it, as it was about 9 a.m., and between the sun above and the earth below we were both streaming with perspiration. We got back to the ship pretty well fagged, and I stayed on board till we left at 3 p.m. We went direct from Tarona to Sandakan, and as we steamed past the north end of the island I counted 18 jets of steam and smoke on the plain where in the morning there had only been two. The volcano itself was wrapped in smoke, and there were heavy clouds of smoke hanging over the plain. . . . . The Dutch controleur told us that they had already recovered 300 bodies, but that it was impossible to estimate the total loss. He said the other side of the island was worse, lava as well as mud having overflowed there, and that whole villages were buried. No lives were lost in Tarona itself, but forty men from there went into the jungle just before the eruption, and only one got back alive. . . . . We got to Sandakan at midnight on the 16th, and stopped a day there. The eruption was distinctly heard at Sandakan, though it is nearly 500 miles from Sangir."

THE WEST INDIAN FAUNA IN SOUTH FLORIDA.

DR. C. H. MERRIAM has lately published a paper on "The Geographical Distribution of Life in North America" (Proc. Biol. Soc. Wash., April, 1892), which should attract attention on account of the important problems discussed, and the interesting and somewhat novel views advanced. On pp. 49–55 there is a review of the faunal relations of Southern Florida, in which Dr. A. R. Wallace is severely criticized for having stated that Florida is, from a biological point of view, essentially North American, and totally distinct in character from Cuba and the Bahamas, from which it is separated by only a narrow strait. The phrase specially attacked is out of "Island Life," as follows: "Between frigid Canada and subtropical Florida there are less marked differences in the animal productions than between Florida and Cuba."[1]

I well remember that some time ago, when I knew next to nothing of the West Indian fauna, this particular phrase seemed to me very erroneous. An American zoologist cannot fail to be struck with the presence of a colony of West Indian forms in Southern Florida, so distinct from the species and genera of the United States. Following Dr. Merriam's enumeration, we see nine genera of tropical birds, hundreds of tropical insects, a dozen or more land shells, many plants, and so forth. It would seem impossible to doubt that Southern Florida should be referred to the West Indian faunal division in the face of such evidence.

But if we examine the matter from the point of view of a West Indian, who is searching for a fauna in Florida, which is identical, or nearly so, with that of the islands, things look very different indeed. Dr. Wallace's reference was to Florida as a whole, the term "subtropical" being used as descriptive of the State, not of the southern coast only, as used by Dr. Merriam. In the map given by Dr. Merriam, about nine-tenths of Florida are coloured orange, to indicate that they belong to the Lower Sonoran Region of the author. Now this, with the Upper Sonoran, which stretches into Canada, north of Lake Erie, forms the Sonoran, one of Dr. Merriam's primary divisions, the distinction of which from the Tropical region he has so well demonstrated. Furthermore, a large part of Canada is coloured blue on the map, to show that it belongs to the Transition Region between the Sonoran and the Borcal. Hence it appears, from Dr. Merriam's own map, and the statements throughout his paper, that by far the greater part of Florida is more allied faunally to portions of Canada than it is to the West Indies, so far exactly confirming the truth of Dr. Wallace's statement.

This will no doubt be readily admitted by Dr. Merriam, who bases his criticisms on the ground that Dr. Wallace had overlooked the existence of a West Indian fauna along the extreme south coast of Florida. We may, therefore, consider the evidence whereby this limited portion of the State is placed in the Tropical division. For convenience, we may allude to this tract as Tropical Florida, using the term tropical to indicate the climate rather than the fauna.

In order to get at the necessary facts, I have compared the birds of the regions under consideration, using Cory's "Birds of the West Indies" as a guide to the ornithology of the several islands.

Dr. Merriam says that "no less than nine" genera of Tropical American birds inhabit Tropical Florida, and cites nineteen species or subspecies of Antillean birds living in the same area, but not further north.

I find on examining and comparing the West Indian statistics,[1] that no less than 51 genera of West Indian land birds *fail* to reach Florida or any other part of North America. These genera are as follows :—

Mimocichla ; Cichlherminia ; *Margarops ;* Ramphocinclus Cinclocerthia ; Leucopera ; Catharopera ; *Microligea ; Teretistris : Glossiptila ; Laletes ; Dulus ;* Calliste ; *Spindalis ; Nesospingus ; Phœnicophilus ; Calyptophilus ;* Saltator ; *Loxigilla ; Melopyrrha ; Loximitris ; Sicalis ; Nesopsar ; Elainia ; Lawrencia ; Blacicus ; Nyctilius ; Siphonorhis ; Hemiprocne ;* Glaucis ; *Lampornis* ; Eulampis ; *Aithurus ;* Thalurania ; *Mellisuga ; Doricha ; Bellona ; Sporadinus ; Priotelus ; Temnotrogon ; Saurothera* ; *Hyetornis; Todus ; Picumnus* ; *Nesoceleus ; Ara ; Chrysotis ; Gymnasio ; Rupornis ; Regerhinus ; Xiphidiopicus.*

Those printed in ordinary type appear to occur in the West Indies only in the Lesser Antilles.

The number of West Indian species not reaching Florida is of course overwhelmingly great, but here the comparison would be unfair, owing to the large number of representative species, on different islands. In order to obtain a just estimate I have therefore made a list of the land birds inhabiting Cuba which do not occur in Tropical Florida, and the result shows one family (*Todidæ*), 18 genera, and 52 species. There are also a few sub-species.

The list is as follows :—

Icterus hypomelas.
Agelaius humeralis.
,, assimilis.
Sturnella hippocrepis.
Quiscalus gundlachii.
,, atroviolaceus.
Corvus nasicus.
,, minutus.
Pitangus caudifasciatus.
* Saurothera merlini.
* Todus multicolor.
* Xiphidiopicus percussus.
Centrurus superciliaris.
Colaptes chrysocaulosus.
* Nesoceleus fernandinæ.
* Mimocichla rubripes.
,, schistacea.
Myiadestes Elizabeth.
Mimus gundlachi. B.
Polioptila lembeyi.
Dendroica petechia (race gundlachi) B.
,, pityophila.
* Teretistris fernandinæ.
,, fornsi.
* Cœreba cyanea.
Myiarchus sagræ. B.
* Blacicus caribœus.
Tyrannus magnirostris.
Antrostomus cubanensis.
Cypselus phœnicolius.
* Hemiprocne zonaris.
Calypte helenæ.
* Sporadinus riccordi. B.
* Priotelus temnurus.
Petrochelidon fulva.
Viveo gundlachi.
* Spindalis pretrei.
* Melopyrrha nigra.
* Pyrrhomitris cucullata.
Euetheia olivacea.
* Ara tricolor.
Conurus euops.
* Chrysotis leucocephala. B.
Asio stygius.
* Gymnasio lawrencii.
Glaucidium siju.
Accipiter gundlachi.
,, fringilloides.
* Regerhinus wilsonii.
Columba corensis.
,, inornata.
Geotrygon caniceps.

The two species of *Columba* are not definitely given as Cuban in Cory's work but I believe they occur there. Species marked with an asterisk are of genera not reaching Florida; species marked "B" also occur in the Bahamas.

The Bahama Islands also have many birds that are not in Tropical Florida, including some genera, as *Doricha* (two species).

It is thus apparent that, so far as the birds are concerned, the arm of sea between Cuba or the Bahamas and the mainland has been very efficient in preventing the mingling of two faunæ, although a limited number of species have crossed it.

To give many other instances would unduly prolong this letter; but one may cite the land shells as a much more striking case. The land mollusca of Cuba and Florida are almost entirely distinct, the small number (about a dozen[2]) of West Indian forms which have reached Florida is really surprising, considering the favourable currents and the proximity of the two areas. Cuba contains numerous generic and subgeneric types, and hundreds of species, which have never reached Florida.[3]

On the other hand, even on the Florida Keys we get such

---

[1] This statement is qualified by a footnote in the new edition of "Island Life," where the existence of some West Indian forms is referred to.

[1] These might be modified in slight details by searching the most recent literature, but Cory's work (1889) is very complete up to the time it was published.

[2] Dr. Merriam cites 20 on Dr. Dall's authority; but several of these are not land shells, but belong to brackish or fresh water.

[3] Thus, Cuba has considerably over 200 species of operculate land-shells which have not reached Florida.

North American types as the subgenera *Polygyra* and *Mesodon* of *Helix* (*H. jejuna*, No Name Key; *H. pustula*, Cedar Keys; *H. carpenteriana*, Key Biscayne; *H. cereolus*, Indian Key, Key West, Egmont Key; *H. septemvolva*, Key West; *H. oppilata*, Cedar Keys (but this is also a Yucatan species); *H. uvulifera*, plentiful on several Keys; *H. auriculata*, Cedar Keys).

How far the birds of Tropical Florida agree with those of the Sonoran region I do not know, having no list at hand from which to glean the facts; but inasmuch as they must greatly exceed nineteen, the number of Antillean forms quoted by Dr. Merriam, it is apparent that the character of the air-fauna cannot be so totally different from that of more northern regions as to justify the proposal to merge it in a different primary faunal division. Dr. Merriam gives a list of the birds which are supposed to be restricted to Southern Florida, comprising two species and seven sub-species; this list emphatically confirms the view that the region in question is really North American (Sonoran), for of the two species, one belongs to a genus which does not occur in the West Indies, and the other to a North American genus which has no endemic West Indian species. The seven sub-species are *all* of North American species, and three of them belong to genera (*Meleagris Cyanocitta*, *Sitta*) which do not exist in the West Indies.

To sum up, the facts seem to be as follows:—The whole of Florida really belongs to the eastern division of the Nearctic region (or to the Sonoran region of Dr. Merriam), but along the southern coast, on land of comparatively recent origin, a number of West Indian forms have appeared, owing to the assistance of currents conveying floating trees, &c., and to the proximity of Cuba and the Bahamas, which has permitted many birds and insects to fly across. These immigrants have formed a distinct colony, but not to any great extent, so far as can be learned, at the expense of the native fauna. The recent appearance of this colony is shown by the fact that (except somewhat doubtfully in the case of a few mollusca) there is at present no tendency to form new endemic species. Mr. Schwarr, who was so impressed with the great number of West Indian insects he found in this region, specially mentions that there were *no endemic forms*.

The northward spread of this colony has doubtless been largely prevented by climate, as stated by Dr. Merriam; but doubtless also quite as largely owing to the *competition of the Sonoran fauna*, for, as Dr. Merriam has himself put it in another connection, "the sustaining capacity of a region is limited; hence such a thing as overcrowding, in the sense of greatly increasing the number of organisms a region can support, is an impossibility."

If climate had been the only barrier, then Tropical Florida should have a fauna like that of Cuba; but so far from doing so, it is still essentially Nearctic, notwithstanding the existence of a very important and interesting West Indian colony. At best it is a transition region.

Under the guidance of Dr. Merriam, researches into the geographical distribution of North American birds and mammals are being energetically carried on; and if I am not mistaken in the above-stated opinions, no doubt information will in due course accumulate that will cause him to withdraw from the position here criticized, and to admit that Dr. Wallace was, in the main, perfectly correct. T. D. A. COCKERELL.

July 31.

"A NEW SECT OF HERO-WORSHIPPERS."

UNDER this title, the *Japan Mail* describes a curious Society, established in Japan, in honour of Isaac Newton, and which is not a new scientific association so much as a new cult. The day of all the year to the members is Christmas Day, being that on which in 1642 the immortal Newton was born. The constitution is of the simplest. The professors, graduates, and students of the mathematical, astronomical, and physical classes of the Tokio University are *ex officio* members; once a member always a member; and there are no others. The Society was launched as one for undergraduates by Messrs. Fujisawa, Tanaka, and Tanakadate, the first brilliant triumvirate of mathematical graduates which the Tokio University gave to the world. In its early days it met in the students' dormitory. But as the undergraduates developed into graduates and assistants, the professors themselves were drawn into the fold, and a more suitable assembly hall was found in the University Observatory. Now, however, that building is devoted to seismological pursuits. At Christmas, 1890, or Newtonmas, 248, for the first time, the members of the *Newtonkai*, or Newton Association, met in the Physical Laboratory of the Imperial University, to hear each other talk, to distribute appropriate gifts, and to lengthen out the small hours with laughter and good cheer. The Society has no President: a portrait of the august Sir Isaac presides over the scene. It keeps no written records, no minutes; but its traditions are simple, and easily handed down from year to year. The entertainment provided is the work of the second-year students, assisted by those of the first year. Each professor is expected to make a little speech, which is sometimes historical, sometimes whimsical, as the individual spirit may prompt; but it must not be suggestive of the background of a blackboard. The meeting in fact is essentially social; and in the preparation of the magic lantern slides, the committee of management lay themselves out for frolic and jest. The picture may represent a comical incident familiar to most of the members, or it may be a pictorial conundrum to guess. It was a fine humour, for instance, which gave a caricature of one student notorious for his indefatigable asking of questions. This youth was shown labouring under a shoulder beam, from which hung two buckets filled to overflowing with points of interrogation; while in the background was seated one of the professors, perfectly aghast as this mathematical labourer approached with his load. After the magic lantern exhibition comes the lottery for presents. This is a great feature, productive of much merriment. Each person draws a paper, which may be blank, but usually has a name on it. This name may be one of the illustrious living, or the still more illustrious dead. Corresponding to each name is an article, which, with all solemnity, is presented to the holder of the paper. The connection between the article and the name is more or less symbolic, or it may rest on a far-fetched pun, to which the Japanese language readily lends itself. Usually the jokes are very technical; but occasionally they appeal to a circle more wide than mathematical. Thus the drawer of "Newton" got an apple, and the drawer of "Franklin" a kite. "Herschell" (Sir John) was represented by a sprig of *Nanten* ("southern heavens," which he surveyed); "Archimedes," by a naked doll supposed to be returning from the bath; while the holder of "Kant-Laplace," got a puff of tobacco smoke blown in his face, symbolic of the nebular hypothesis. Some time ago it was pointed out by a European member of the *Kai* that in holding the "Newtonmas" on Christmas Day the members were guilty of a chronological crime hardly to be excused in men trained in the accurate school of Newton. For although he was registered as being born on Christmas Day, 1642, it was Christmas Day, old style. In all strictness he was born on January 5, 1643. But the great convenience of having the *fête* at the beginning rather than towards the end of the winter vacation, and the avoidance of clashing with Japanese New Year festivities, were sufficient to outweigh all other considerations whatsoever. Besides, did not Newton himself hold his birthday on Christmas Day? Why, then, should his admirers hold it on any other? After all, concludes the Yokohama journal, the peculiar interest of the "Newtonmas" lies in its existence. Only to the hero-worshipping Japanese has it occurred thus to pay honour to the memory of the greatest mathematical sage of all time. Very few English-speaking naturalists, to use the word in its widest and legitimate sense, are even aware that Christmas Day in 1642 beheld the birth of Newton. It is possible that nearly fifty years ago a bicentenary *fête* was held in Cambridge; and it is very probable that about fifty years hence Newton's tercentenary will be celebrated in England—perhaps over all the civilized world. But an annual celebration by a Newton Club outside Japan is a thing not to be dreamed of, unless Japan influences the hero-worshipping instinct of the Western people as profoundly as she has influenced their æsthetic taste.

SCIENTIFIC SERIALS.

Royal Society of Victoria, Vol. 3 (N.S.), *Proceedings*, Part I. contains Notes on West Australian oology, by A. J. Campbell (Pls. 1 and 2); On some Victorian fishes, with descriptions of *Cristiceps wilsoni*, *C. phillipi*, *Syngnathus phillipi*, and *Trip-*

terygium macleayanum (Pl. 3) by A. H. Lucas; Anthropology in Australia, by A. W. Howitt; On the nomenclature of chick-embryos (Pls. 4–7). Instead of indicating the stages in the development of the chick by the number of hours or days, which is unsatisfactory, as different eggs incubated for the same length of time will frequently be found to contain embryos which have reached quite different stages of development, the stages are marked based upon the external form, and each is designated by a letter of the alphabet. On some Victorian Land Planarians, by Prof. W. B. Spencer (Pls. 11 and 12), enumerates ten species of Geoplana and describes *G. dendyi*, sp. n., and *G. frosti*, sp. n.; all the species are figured in two admirably executed coloured plates. On the movements of the heart of *Hoplocephalus superbus* in and out of the body, by Dr. McAlpine; On a Nematode from the stomach of *Hoplocephalus superbus*, and on a fluke parasitic in the respiratory and alimentary systems of the same. Neither parasites are named but the Nematode (Ascaris) is figured on pl. 8. On the presence of amœboid corpuscles in the liquid discharged from the nephridial apertures and oral papillæ of Peripatus, by A. Dendy; On the shell money of New Britain, by R. H. Rickard; On the Dukduk Association of New Britain; Notes on the miocene strata of Jemmy's Point and on the older tertiary at Bairnsdale, by J. Dennant. Some new or little known Polzyoa, by P. H. MacGillivray (Pls. 9 and 10); Notes on the marine rocks underlying Warrnambool, by G. S. Griffiths.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, August 29.—M. Duchartre in the chair.—Observations of the new planet M. Wolf, made at the observatory of Paris (west equatorial), by M. G. Bigourdan. From observations of comparison stars, the R.A. of the planet in question on August 27, at 12h. 20m. 33s. p.m. Paris mean time, was 22h. 41m. 24·95s., its apparent declination − 10° 25′ 51″·8, and its magnitude 12·5.—Measures of the diameter of Mars, by M. Camille Flammarion. To settle the divergence between the values of the diameters of Mars as predicted by the *Nautical Almanac*, the *Connaissance des Temps*, and Marth's "Ephémérides," measurements were taken with the 24cm. equatorial of the Juvisy observatory, resulting in values ranging from 24″·50 to 24″·91. These confirm Marth's calculations, while the other two ephemerides are about 5″ in excess, based as they are upon Leverrier's tables instead of Hartwig's.—On the solar phenomena observed at the Royal Observatory of the Roman College during the second quarter of 1892, by M. P. Tacchini.—On the bacterian origin of the bilious fever of hot countries, by M. Domingos Freire. A microscopic comparison of the germs of the yellow fever with those of the somewhat similar bilious fever of tropical countries shows that the former is due to a micrococcus, which is round, highly refractive, and easily coloured by fuchsine, methyl blue, &c., whereas the bilious fever is originated by a bacillus which the writer has succeeded in cultivating. It is about nine microns long and three broad. It is motionless, and accompanied by numerous moving spores. Each bacillus undergoes rapid segmentation into two parts, which give rise to terminal spores. It has been found possible to produce the disease in a pig by inoculation.—On the comparative assimilation of plants of the same species, developed in the sun and in the shade respectively, by M. L. Géneau de Lamarlière. A series of quantitative results, showing that under similar external conditions the decomposition of carbonic acid varies in intensity, for leaves of the same species, according to the conditions of development of these leaves; and that the leaves of a species developed in the sun, all other conditions being equal, decompose the carbonic acid of the air more energetically than those developed in the shade.—On the present eruption of Etna, by M. Wallerant. The eruption of 1892, without having the importance of that of 1865, is, from several points of view, superior to that of 1886; the flows of lava are more extended and the craters more numerous. On July 8 the volcano gave its usual warnings. Thick columns of black smoke emerged from the principal crater, and earthshocks were felt as far as Catania. On the following day the eruption began in earnest. Two openings appeared a short distance apart, one of which only gave off steam, while the other gave rise to a flow of lava which passed westwards of Monte Nero, and which has been called the western stream. It was not till after the flow had ceased that four volcanic cones arose successively from north to south at a distance of about 60 m. to the east of this cleft. Another flow of lava passed to the east of Monte Nero, and was called the eastern stream. For about a month the eruption followed its normal course; the lava continued to flow and the cones increased in height. But on August 9 important modifications took place. The ejections diminished and the explosions ceased. It was thought that the disturbance was dying out, but on the 11th such an eruption of steam took place that Etna disappeared entirely in an absolutely opaque cloud. At the same time it was found that the lava, leaving the first tracks, had taken a new path across the vineyards. In the morning of the 12th the opening of a new crater in the line of the preceding ones was found in the act of building up a cone. The previous evening the observers had passed over the same spot and had found small vents giving off vapours, but nothing to indicate the formation of a crater in so short a time. The formation of this crater was accompanied by a complete cessation of the ejections from the second volcanic cone, which had been very violent. The eruption thus seemed to have entered a new stage of development.
